BHIVA guidelines for the treatment of HIV-1 positive adults with antiretroviral therapy 2012

30th April 2012
Writing Group

Dr Ian Williams  Senior Lecturer, University College London and Honorary Consultant Physician, Central and North West London NHS Foundation Trust (Chair)

Dr Duncan Churchill  Consultant Physician in HIV and Genitourinary Medicine, Brighton and Sussex University Hospitals NHS Trust (Vice Chair)

Prof Jane Anderson  Consultant Physician and Director of the Centre for the Study of Sexual Health and HIV, Homerton University Hospital NHS Foundation Trust, London

Dr Marta Boffito  Consultant Physician in HIV Medicine, Chelsea and Westminster Hospital NHS Foundation Trust, London

Prof Mark Bower  Professor of Oncology, Imperial College London and Consultant Physician in Medical Oncology, Chelsea and Westminster Hospital NHS Foundation Trust, London

Mr Gus Cairns  UK Community Advisory Board representative/HIV treatment advocates network

Dr Kate Cwynarski  Consultant Physician in Haematology, Royal Free London NHS Foundation Trust

Dr Simon Edwards  Consultant Physician in HIV and Genitourinary Medicine, Central and North West London NHS Foundation Trust (Section lead)

Dr Sarah Fidler  Senior Lecturer in HIV and Genitourinary Medicine, Imperial College School of Medicine at St Mary's, London

Dr Martin Fisher  Consultant Physician in HIV and Genitourinary Medicine, Brighton and Sussex University Hospitals NHS Trust (Section Lead)

Dr Andrew Freedman  Reader in Infectious Diseases and Honorary Consultant Physician, Cardiff University School of Medicine

Prof Anna Maria Geretti  Professor of Virology and Infectious Diseases, Institute of Infection and Global Health, University of Liverpool

Dr Yvonne Gilleece  Consultant Physician in HIV and Genitourinary Medicine, Brighton and Sussex University Hospitals NHS Trust

Prof Rob Horne  Professor of Behavioural Medicine, Head of Department of Practice and Policy and Director of Centre for Behavioural Medicine, University College London

Prof Margaret Johnson  Professor in HIV Medicine and Clinical Director of HIV/AIDS Services, Royal Free London NHS Foundation Trust

Prof Saye Khoo  Honorary Consultant Physician in Infectious Diseases and Professor of Translational Medicine, University of Liverpool

Prof Clifford Leen  Consultant Physician in Infectious Diseases, Western General Hospital, Edinburgh and Honorary Professor Infectious Diseases, Edinburgh University

Mr Neal Marshall  Specialist HIV Pharmacist, Royal Free London-NHS Foundation Trust

Dr Mark Nelson  Consultant Physician, Chelsea and Westminster Hospital NHS Foundation Trust, London

Dr Chloe Orkin  Consultant Physician and Lead for HIV Research, Barts Health NHS Trust, London
Dr Nicholas Paton  
Senior Clinical Scientist, Medical Research Council Clinical Trials Unit, London

Prof Andrew Phillips  
Professor of Epidemiology, University College London

Dr Frank Post  
Senior Lecturer, King's College London and Honorary Consultant Physician in Infectious Diseases, King’s College Hospital NHS Foundation Trust, London

Dr Anton Pozniak  
Consultant Physician, Chelsea and Westminster Hospital NHS Foundation Trust and Honorary Senior Lecturer, Imperial College London

Prof Caroline Sabin  
Professor of Medical Statistics and Epidemiology, University College London

Mr Roy Trevelion  
UK Community Advisory Board representative/HIV treatment advocates network

Dr Andrew Ustianowski  
Consultant in Infectious Diseases and Tropical Medicine and Associate Clinical Director, North Manchester General Hospital

Dr John Walsh  
Consultant Physician in HIV and Sexual Health, Imperial College Healthcare NHS Trust, London

Dr Laura Waters  
Consultant Physician in HIV and Genitourinary Medicine, Central and North West London NHS Foundation Trust

Dr Edmund Wilkins  
Consultant Physician in Infectious Diseases and Director of the HIV Research Unit, North Manchester General Hospital (Section Lead)

Dr Alan Winston  
Consultant Physician, Imperial College Healthcare NHS Trust and Senior Lecturer in HIV and Genitourinary Medicine, Imperial College London

Dr Mike Youle  
Director of HIV Clinical Research, Royal Free London NHS Foundation Trust
BHIVA guidelines for the treatment of HIV-1 positive adults with antiretroviral therapy 2012

1. Introduction

1.1 Scope and purpose

The overall purpose of these guidelines is to provide guidance on best clinical practice in the treatment and management of adults with HIV infection with antiretroviral therapy (ART). The scope includes guidance on the initiation of ART in those previously naïve to therapy, support of patients on treatment, management of patients experiencing virological failure and recommendations in specific patient populations where other factors need to be taken into consideration. The guidelines are aimed at clinical professionals directly involved with and responsible for the care of adults with HIV infection and at community advocates responsible for promoting the best interests and care of HIV positive adults. They should be read in conjunction with other published BHIVA guidelines.

1.2 Methodology

1.2.1 Guideline development process

BHIVA revised and updated the association’s guideline development manual in 2011 [1]. BHIVA has adopted the modified Grading of Recommendations Assessment, Development and Evaluation (GRADE) system for the assessment, evaluation and grading of evidence and the development of recommendations [2,3]. Full details of the guideline development process including conflict of interest policy are outlined in the manual.

The scope, purpose and guideline topics were agreed by the Writing Group. Questions concerning each guideline topic were drafted and a systematic literature review undertaken by an information scientist. Details of the search questions and strategy (including the definition of populations, interventions and outcomes) are outlined in Appendix 2. BHIVA adult ART guidelines were last published in 2008 [4]. For the 2012 guidelines the literature search dates were 1st January 2008 to 16th September 2011 and included Medline, Embase and the Cochrane library. Abstracts from selected conferences (see Appendix 2) were searched between 1st January 2009 and 16th September 2011. For each topic and health care question, evidence was identified and evaluated by Writing Group members with expertise in the field. Using the modified GRADE system (Appendix 1), panel members were responsible for assessing and grading the quality of evidence for predefined outcomes across studies and developing and grading the strength of recommendations. An important aspect of evaluating evidence is an understanding of the design and analysis of clinical trials including the use of surrogate marker data.
For a number of questions, GRADE evidence profile and summary of findings tables were constructed, using predefined and rated treatment outcomes (Appendix 3), to help achieve consensus for key recommendations and aid transparency of the process. Prior to final approval by the Writing Group, the guidelines were published on line for public consultation and external peer review commissioned.

1.2.2 Patient involvement

BHIVA views the involvement of patient and community representatives in the guideline development process as essential. The Writing Group included two patient representatives appointed through the UK HIV Community Advisory Board (UK CAB) who were involved in all aspects of the guideline development process. In addition two meetings with patients and community representatives were held to discuss and receive feedback and comment on the proposed guideline recommendations. The first was held prior to the Writing Group’s consensus meeting and the second as part of the public consultation process.

1.2.3 GRADE

The GRADE Working Group [3] has developed an approach to grading evidence that moves away from initial reliance on study design to consider the overall quality of evidence across outcomes. BHIVA has adopted the modified GRADE system for the association’s guideline development.

The advantages of the modified GRADE system are: (i) the grading system provides an informative, transparent summary for clinicians, patients and policy makers by combining an explicit evaluation of the strength of the recommendation with a judgment of the quality of the evidence for each recommendation; (ii) the two-level grading system of recommendations has the merit of simplicity and provides clear direction to patients, clinicians and policy makers.

A Grade 1 recommendation is a strong recommendation to do (or not do) something, where the benefits clearly outweigh the risks (or vice versa) for most, if not all patients. Most clinicians and patients should and would want to follow a strong recommendation unless there is a clear rationale for an alternative approach. A strong recommendation usually starts with the standard wording ‘we recommend’.

A Grade 2 recommendation is a weaker or conditional recommendation, where the risks and benefits are more closely balanced or are more uncertain. Most clinicians and patients would want to follow a weak or conditional recommendation but many would not. Alternative approaches or strategies may be reasonable depending on the individual patient’s circumstances, preferences and values. A weak or conditional recommendation usually starts with the standard wording ‘we suggest’.

The strength of a recommendation is determined not only by the quality of evidence for defined outcomes but also the balance between desirable and undesirable effects of a treatment or intervention, differences in values and preferences and where appropriate resource use. Each recommendation concerns a defined target population and is actionable.

The quality of evidence is graded from A to D and for the purpose of these guidelines is defined as the following:
Grade A evidence means high-quality evidence that comes from consistent results from well-performed randomised controlled trials (RCTs), or overwhelming evidence of some other sort (such as well-executed observational studies with consistent strong effects and exclusion of all potential source of bias). Grade A implies confidence that the true effect lies close to the estimate of the effect.

Grade B evidence means moderate-quality evidence from randomised trials that suffer from serious flaws in conduct, inconsistency, indirectness, imprecise estimates, reporting bias, or some combination of these limitations, or from other study designs with special strengths such as observational studies with consistent effects and exclusion of most potential source of bias.

Grade C evidence means low-quality evidence from controlled trials with several very serious limitations or observational studies with limited evidence on effects and exclusion of most potential source of bias.

Grade D evidence on the other hand is based only on case studies, expert judgment or observational studies with inconsistent effects and a potential for substantial bias, such that there is likely to be little confidence in the effect estimate.

1.2.4 Good practice points

In addition to graded recommendations, the BHIVA Writing Group has also included good practice points (GPP), which are recommendations based on the clinical judgment and experience of the working group. GPPs emphasise an area of important clinical practice for which there is not, nor is there likely to be, any significant research evidence. They address an aspect of treatment and care that is regarded as such sound clinical practice that health care professionals are unlikely to question it and where the alternative recommendation is deemed unacceptable. It must be emphasised that GPPs are not an alternative to evidence-based recommendations.

1.2.5 Dissemination and implementation

The following measures have/will be undertaken to disseminate and aid implementation of the guidelines:
- E-publication on the BHIVA website and the journal *HIV Medicine*
- Publication in *HIV Medicine*
- Shortened version detailing concise summary of recommendations
- E-learning module accredited for CME
- Educational slide set to support local and regional educational meetings
- National BHIVA audit programme

1.2.6 Guideline updates and date of next review

The guidelines will be next fully updated and revised in 2014. The Writing Group will however continue to meet regularly to consider new information from high quality studies and publish amendments and addendums to the current recommendations prior to the full revision date where this is thought to be clinically important to ensure continued best clinical practice.
1.3 Treatment aims

The primary aim of ART is the prevention of the mortality and morbidity associated with chronic HIV infection at low cost of drug toxicity. Treatment should improve the physical and psychological well being of people living with HIV infection. The effectiveness and tolerability of ART has improved significantly over the last 15 years, with the overwhelming majority of patients attending HIV services in the UK and receiving ART experiencing long-term virological suppression and good treatment outcomes [5] which compare very favourably with other developed countries.

Recent data has shown that the life expectancy in the UK of someone living with HIV infection has improved significantly over recent years but is still about 13 years less than that of the UK population [6]. For someone aged 20 years starting ART, life expectancy increased from 30.0 to 45.8 years from 1996–9 to 2006–8. The impact of starting ART late is large with up to 15 years of reduced life expectancy if ART is started later than the current BHIVA guidelines recommend. Other data has shown for HIV positive men who have sex with men (MSM) living in a developed country with extensive access to HIV care and assuming a high rate of HIV diagnosis the projected life expectancy was 75 years [7]. The authors concluded that the greatest risk of excess mortality is due to delays in HIV diagnosis. Decreasing late diagnosis, starting ART earlier at recommended CD4 count levels, maintaining patients in care and reducing long-term drug toxicity and non-AIDS co-morbidities are crucial to further improving life expectancy and the well being of people living with HIV infection.

A further aim of treatment is the reduction in the sexual transmission of HIV and for some patients may be the primary aim. The use of ART to prevent mother to child transmission is universally accepted and best practice is addressed in the BHIVA pregnancy guidelines. Recently, the size of the effect of ART on reducing the risk of sexual transmission of HIV has been estimated at greater than 95% [8,9]. At a population level, ART may be potentially important in reducing the incidence of HIV infection. ART is usually started for the health benefit of the individual, but in certain circumstances it may be beneficial to start ART to primarily reduce the risk of onward sexual transmission of HIV.

1.4 Resource use

ART is extremely cost effective and compares favourably with the cost of management of many other chronic diseases. Estimates of the cost effectiveness of antiretroviral therapy have been assessed in studies in North America and Europe [10–12]. Their findings have been consistent with an estimated incremental cost effectiveness ratio of about US$20,000 per quality adjusted life year for combination antiretroviral therapy compared to no therapy based on drug costs and treatment patterns in the USA and Europe [13].

The number of people living with HIV in the UK continues to increase and by the end of 2010 was estimated to be 91,500 of whom 24% were undiagnosed. Of those diagnosed, 69,400 accessed HIV services in 2010 of whom 82% were on ART [5]. With ongoing HIV transmission, increased HIV testing and a reduction in the undiagnosed fraction the number of people diagnosed with HIV and accessing HIV services will continue to increase. It has been estimated that the annual population treatment and care costs rose from £104 million in 1997 to £483 million in 2006, rising to a projected annual cost of £721 million in 2013 [14]. It is likely this
estimated projected cost is an overestimate due to various factors including earlier diagnosis and a lower proportion of patients with symptoms. However in the current economic climate containing and reducing annual costs without affecting the current high standards of care and treatment outcomes will be an immense challenge to commissioners, health care professionals and patients alike. A collaborative approach is required.

In the UK, higher annual treatment and care costs have been associated with late diagnosis and initiation of ART at lower CD4 counts than the BHIVA guidelines recommend [15,16]. In addition to earlier diagnosis and initiation of ART, reducing inpatient episodes, decreasing drug toxicity, preventing HIV-associated co-morbidities and innovations in models of care are likely to have a beneficial effect on annual costs. However the cost of antiretroviral drugs remains the major factor contributing to treatment and care costs. With the future availability of generic drugs and the introduction of a standard tariff for HIV services (in England) clinicians and patients will be faced with difficult choices about the value and benefit of different antiretroviral drugs.

The BHIVA Writing Group recognises that cost of drugs is an important issue in the choice of ART regimens There is limited cost effectiveness data in the UK comparing different antiretroviral drugs and for this reason the Writing Group did not include cost effectiveness as an outcome in ART comparisons. However the Writing Group believes that decreasing the risk of virological failure, drug resistance and drug-associated toxicity are likely to have a beneficial impact on long-term cost effectiveness and resource use. In the setting of equivalent virological efficacy, determining the acceptable threshold at which differences in the risk of toxicity, tolerability and convenience outweigh differences in resource use and cost will be important. These thresholds may differ amongst clinicians and patients alike.

In developing the recommendations in these guidelines the Writing Group has taken into account differences in critical treatment outcomes between different drug regimens in determining preferred and alternative treatment regimens. The Writing Group recognises and supports that commissioning arrangements and local drug costs will and should influence ART choice where outcomes, across a range of clinical measures, are equivalent between individual drugs in the treatment of defined patient populations. The Writing Group however believes that reducing treatment costs should not be at the cost of an increased risk of poorer treatment outcomes and quality of care, not least as these are likely to have a detrimental impact on long-term cost.

1.5 Implications for research

In reviewing quality of evidence, guidelines will identify areas of treatment and care where there is either an absence of evidence or limited confidence in the size of effect to influence choice of treatments or determine treatment and management strategies. For this reason it is not the intention of these guidelines to stifle clinical research but help promote continued research with the aim to further improve clinical care and treatment outcomes. The Writing Group supports the development and provision of HIV clinical trials within the UK and participation in a clinical trial should be open and offered to patients where appropriate.

2. Recommendations and auditable outcomes

2.1 Recommendations (GRADE)

*Patient involvement in decision making (Section 3)*

<table>
<thead>
<tr>
<th>• 3 1</th>
<th>• We recommend patients are given the opportunity to be involved in making decisions about their treatment.</th>
<th>• GPP</th>
</tr>
</thead>
</table>

*When to start (Section 4)*

**Chronic infection**

<table>
<thead>
<tr>
<th>• 4 1</th>
<th>• We recommend patients with chronic infection start ART if the CD4 count is ( \leq 350 \text{ cells/( \mu \text{L} )} ): it is important not to delay treatment initiation if the CD4 cell count is close to this threshold.</th>
<th>• 1A</th>
</tr>
</thead>
</table>

| • | • We recommend patients with the following conditions start ART:  
  • AIDS diagnosis (e.g. Kaposi’s sarcoma) irrespective of CD4 cell count.  
  • HIV-related co-morbidity including HIVAN, ITP, symptomatic HIV-associated neurocognitive disorders irrespective of CD4 cell count.  
  • Co-infection with hepatitis B virus if the CD4 count is \( \leq 500 \text{ cells/\( \mu \text{L} \)} \) (see Section 8.2.2 Hepatitis B)  
  • Co-infection with hepatitis C virus if the CD4 count is \( \leq 500 \text{ cells/\( \mu \text{L} \)} \) (Section 8.2.3 Hepatitis C)  
  • Non-AIDS defining malignancies requiring immunosuppressive radiotherapy or chemotherapy (Section 8.3.2 When to start ART: non-AIDS-defining malignancies) | • 1A  
  • 1C  
  • 1B  
  • 1C  
  • 1C |
|---|---|---|

| • | • We suggest patients with the following conditions start ART:  
  • Co-infection with hepatitis B virus if the CD4 count is >500 cells/\( \mu \text{L} \) and treatment of hepatitis B is indicated (see Section 8.2.2 Hepatitis B) | • 2B |
|---|---|---|
Patients presenting with AIDS or a major infection

- We recommend patients presenting with an AIDS-defining infection, or with a serious bacterial infection and a CD4 count <200 cells/µL, start ART within 2 weeks of initiation of specific antimicrobial chemotherapy.  

| 1B |

Treatment of primary HIV infection

- We recommend patients presenting with primary HIV infection and meeting any one of the following criteria start ART:
  - Neurological involvement
  - Any AIDS-defining illness
  - Confirmed CD4 cell count <350 cells/µL

| 1D |

| 1A |

| 1C |

Treatment to reduce transmission

- We recommend the evidence that treatment with ART lowers the risk of transmission is discussed with all patients, and an assessment of the current risk of transmission to others is made at the time of this discussion.

| GPP |

- We recommend following discussion, if a patient with a CD4 count above 350 cell/µL wishes to start ART to reduce the risk of transmission to partners, this decision is respected and ART is started.

| GPP |

What to start (Section 5)

5.1 We recommend therapy naïve patients start ART containing two NRTIs and either a ritonavir-boosted protease inhibitor, or a NNRTI or an integrase inhibitor

| 1A |

Pharmacology

Drug interactions

| 6.2.1 | We recommend that potential adverse pharmacokinetic interactions between antiretroviral drugs and other concomitant medications are checked before administration (with tools such as www.hiv-druginteractions.org) | GPP |

Therapeutic drug monitoring (TDM)

| 6.2.2 | We recommend against the unselected use of TDM | GPP |

Stopping therapy: pharmacological considerations

| 6.2.3 | We recommend patients stopping ART containing a NNRTI in combination with a NRTI backbone replace all drugs with a protease inhibitor (lopinavir/ritonavir) for four weeks. | 1C |
|       | We recommend patients stopping a PI-containing regimen stop all drugs simultaneously and no replacement is required (1C) | 1C |

Switching ART in virological suppression

Switching ARVs in combination ART
### BHIVA guidelines for the treatment of HIV-1 positive adults with antiretroviral therapy 2012

#### 6.3.2
We recommend in patients on suppressive ART regimens, consideration is given to differences in side effect profile, drug–drug interactions and drug resistance patterns before switching any ARV component.

GPP

<table>
<thead>
<tr>
<th>We recommend in patients with prior NRTI resistance mutations, against switching a ritonavir boosted PI to either a NNRTI or an INI as the third agent.</th>
<th>1B</th>
</tr>
</thead>
</table>

### Protease inhibitor monotherapy

#### 6.3.3
We recommend continuing standard combination ART as the maintenance strategy in virologically suppressed patients (1C). There is insufficient data to recommend PI/r monotherapy in this clinical situation.

1C

<table>

### Hepatitis B: when to start

#### 8.2.2.1

We recommend patients with HIV and hepatitis B virus co-infection who have a CD4 count between 350–500 cells/µL start ART

1C

We suggest patients with HIV and hepatitis B virus co-infection who have a CD4 count >500 cells/µL and who require treatment for their hepatitis B start ART

2C

### Hepatitis B: what to start

#### 8.2.2.2

We recommend patients with HIV and hepatitis B virus co-infection who start ART include tenofovir and emtricitabine as part of their ART regimen, if there are no contraindications for either drug

1A

### Hepatitis C: when to start ART

#### 8.2.3.1

We recommend patients with HIV and hepatitis C virus co-infection be assessed for HCV treatment (GPP)

GPP

We recommend patients with HIV and hepatitis C virus co-infection and CD4 count between 350-500 cells/µL start ART: (i) immediately if HCV treatment is deferred, (ii) after initiation of HCV treatment if this is starting immediately.¹

1C

We recommend patients with HIV and hepatitis C virus co-infection and CD4 count <350 cells/µ/L start ART before HCV treatment

1B
### Hepatitis C: what to start

| 8.2.3.2 | We recommend that potential pharmacokinetic interactions between antiretrovirals and anti-hepatitis agents are checked prior to administration (with tools such as: http://www.hep-druginteractions.org) | GPP |

### HIV-related cancers: when to start

| 8.3.1. | We recommend starting ART in HIV positive patients with Kaposi sarcoma | 1A |
|        | We recommend starting ART in HIV positive patients with non-Hodgkin lymphoma | 1B |
|        | We suggest starting ART in HIV positive patients with cervical cancer | 1C |
|        | We recommend starting ART in HIV positive patients who are commencing radiotherapy or chemotherapy for cervical cancer | 1D |
| 8.3.2  | We suggest starting ART in HIV positive patients with non-AIDS defining malignancies | 2C |
|        | We recommend starting ART in HIV positive patients who are commencing immunosuppressive radiotherapy or chemotherapy for non-AIDS defining malignancies | 1C |

### HIV related cancers: what to start

| 8.3.3  | We recommend that potential pharmacokinetic interactions between antiretrovirals and systemic anticancer therapy are checked prior to administration (with tools such as: http://www.hiv-druginteractions.org) | GPP |
|        | We suggest avoiding ritonavir-boosted ART in HIV positive patients who are to receive cytotoxic chemotherapy agents that are metabolised by the CYP450 enzyme system | 2C |
|        | We recommend against the use of atazanavir in HIV positive patients who are to receive irinotecan | 1C |
|        | We suggest avoiding antiretroviral agents in HIV positive patients who are to receive cytotoxic chemotherapy agents that have overlapping toxicities | 2C |

### HIV-associated neurocognitive impairment: when to start

| 8.4.2  | We recommend patients with symptomatic HIV-associated neurocognitive | 1C |
disorders start ART irrespective of CD4+ lymphocyte count

### HIV-associated neurocognitive impairment: what to start

| 8.4.3 | We recommend patients with HIV-associated NC disorders start standard combination ART regimens. | 1C |

### HIV-associated neurocognitive impairment: modification of antiretroviral therapy

| 8.4.4 | In patients with ongoing or worsening NC impairment despite ART we recommend the following best practice management | GPP |
|       | • Best practice management should include |
|       | • Re-assessment for confounding conditions |
|       | • Assessment of CSF HIV RNA, CSF HIV genotropism and genotyping of CSF HIV RNA |
|       | • In subjects with detectable CSF HIV RNA, modifications to antiretroviral therapy should be based on plasma and CSF genotypic and genotropism results |

### Chronic kidney disease: when to start

| 8.5.1 | We recommend patients with HIV-associated nephropathy (HIVAN) start ART immediately irrespective of CD4 cell count | 1C |
|       | We recommend patients with end-stage kidney disease who are suitable candidates for renal transplantation start ART irrespective of CD4 cell count (1C) | 1C |

### Chronic kidney disease: what to start

| 8.5.2 | We recommend against the use of antiretroviral drugs that are potentially nephrotoxic, in patients with stages 3–5 CKD if acceptable alternative antiretroviral agents are available. | GPP |
|       | We recommend dose adjustment of renally cleared antiretroviral drugs in patients with reduced renal function. | GPP |

### Cardiovascular disease: what to start

| 8.6.4 | We suggest avoiding: abacavir, fosamprenavir/ritonavir and | 2C |
lopinavir/ritonavir in patients with a high CVD risk, if acceptable alternative antiretroviral drugs are available.

### Women: when to start

**8.7.2** We recommend therapy naïve HIV positive women who are not pregnant start ART according to the same indicators as in men (See Section 3: When to Start)  

<table>
<thead>
<tr>
<th><strong>1A</strong></th>
</tr>
</thead>
</table>

### Women: what to start

**8.7.3** We recommend therapy naïve HIV positive women start ART containing two NRTIs and either a ritonavir-boosted protease inhibitor, or a NNRTI or an integrase inhibitor, as per therapy naïve HIV positive men.

<table>
<thead>
<tr>
<th><strong>1A</strong></th>
</tr>
</thead>
</table>

We recommend therapy naïve HIV positive women start ART with preferred or alternative NRTI backbone and third agent as per therapy naïve HIV positive men (See Section 5.1: What to start: summary recommendations).

Factors such as potential side effects, co-morbidities, drug interactions, patient preference and dosing convenience need to be considered in selecting ART in individual women.

<table>
<thead>
<tr>
<th><strong>1A</strong></th>
</tr>
</thead>
</table>

We recommend both HIV positive women of child bearing potential and health care professionals who prescribe ART are conversant with the benefits and risks of ARV agents for both the health of the HIV positive women and for that of an unborn child

<table>
<thead>
<tr>
<th><strong>GPP</strong></th>
</tr>
</thead>
</table>

We recommend that potential pharmacokinetic interactions between antiretrovirals, hormonal contraceptive agents and hormone replacement therapy are checked prior to administration (with tools such as: [http://www.hiv-druginteractions.org](http://www.hiv-druginteractions.org))

<table>
<thead>
<tr>
<th><strong>GPP</strong></th>
</tr>
</thead>
</table>
2.2 Summary of auditable measures

Percentage of patients who confirm they have been given the opportunity to be involved in making decisions about their treatment

Proportion of patients with CD4 count <350 cells/µL not on ART

Proportion of patients with CD4 count >350 cells/µL and an indication to start ART on ART

Proportion of patients presenting with an AIDS defining infection or with a serious bacterial infection and a CD4 count <200 cells/µL started on ART within 2 weeks of initiation of specific antimicrobial chemotherapy.

Proportion of patients presenting with primary HIV infection and either neurological involvement or an AIDS defining illness or confirmed CD4 count <350 cells/µL started on ART

Record in patient’s notes of discussion, treatment with ART lowers risk of HIV transmission and an assessment of current risk of transmission.

Proportion of therapy naïve patients not starting ART containing 2 NRTIs and either a PI/r or a NNRTI or an INI (preferred or alternative agents)

Proportion of patients starting ART with either tenofovir/emtricitabine or abacavir/lamivudine as the NRTI backbone

Proportion of patients starting ART with either atazanavir/r, or darunvair/r, or efavirenz or raltegravir as the third agent

Proportion of patients with undetectable VL <50 copies/ml at six months and at 12 months after starting ART

Proportion of patients who switch therapy in the first 6 and 12 months

Record in patient’s notes of HLA B5701 status prior to starting abacavir

Record in patient’s notes of discussion and assessment of adherence and potential barriers to, prior to starting a new ART regimen and whilst on ART

Record in patient’s notes of provision or offer of adherence support

Record in patient’s notes of potential adverse pharmacokinetic interactions between antiretroviral drugs and other concomitant medications

Proportion of patients with undetectable viral load on ART who on stopping a regimen containing a NNRTI in combination with a NRTI backbone, are switched to a PI/r for four weeks.

Number of patients with an undetectable VL on current regimen and documented prior NRTI resistance who have switched a PI/r to either a NNRTI or an INI as the third agent
Number of patients on PI/r monotherapy as ART maintenance strategy in virologically suppressed patients and record of rationale

Record in patient’s notes of resistance result at ART initiation (if available) and at first viral load >400 copies/ml and/or before switch

Record in patient’s notes of adherence assessment and tolerability/toxicity to ART, in patients’ experiencing virological failure or repeated viral blips

Number of patients experiencing virological failure on current ART regimen

Proportion of patients experiencing virological failure switched to a new suppressive regimen within 6 months

Proportion of patients on ART with prior documented HIV drug resistance with VL <50 copies/ml

Record of patients with three class virological failure with or without three class resistance referred/discussed in MDT with expert advice

Proportion of patients with TB and CD4 count <100 cells/µL started on ART within 2 weeks of starting Tb therapy

Proportion of patients with active TB on anti-tuberculosis therapy started on ART containing efavirenz and tenofovir and emtricitabine

Proportion of patients with HIV and hepatitis B virus co-infection with CD4 counts <500 cells/µL on ART

Proportion of patients with HIV and hepatitis B virus co-infection starting tenofovir and emtricitabine as part of their first ART regimen

Proportion of patients with HIV and Hepatitis C virus co-infection and CD4 counts <500 cells/µL on ART

Record in patient’s notes of potential pharmacokinetic interactions between antiretrovirals and ant-viral hepatitis C agents

Proportion of patients with an AIDS defining malignancy on ART

Proportion of patients with a non-AIDS defining malignancy on ART

Record in patient’s notes of potential pharmacokinetic drug interactions between antiretrovirals and systemic anti-cancer therapy

Proportion of patients with symptomatic HIV associated neurocognitive disorders on ART

Proportion of patients with HIV associated NC disorders on ART containing two NRTIs and either a NNRTI or a PI/r or a INI

Proportion of patients with HIV associated nephropathy (HIVAN) started on ART within 2 weeks of diagnosis of CKD

Number of patients with CKD stages 3-5 on ARVs that are potentially nephrotoxic and record of rationale
Record in patient’s notes of the calculated dose of renally cleared ARVs in patients with CKD stage 3 or greater

Number of patients with high CVD risk on either abacavir or fosamprenavir/ritonavir or lopinavir/ritonavir and record of rationale

Proportion of HIV positive women with CD4 cell count <350 cells/µL not on ART
3. Patient involvement in decision making

3.1 Recommendations

We recommend patients are given the opportunity to be involved in making decisions about their treatment. (GPP)

Provision of treatment support resources should include in-house, independent and community information providers and peer support resources.

**Auditable measure**

Percentage of patients who confirm they have been given the opportunity to be involved in making decisions about their treatment

3.2 Rationale

Patients should be given the opportunity to be involved in making decisions about their treatment [1]. Studies show that trust, a good quality relationship and good communication skills between doctor and patient are associated with better adherence and treatment outcomes in HIV and in other disease areas [2–6].

Studies have shown that patient beliefs about the necessity, efficacy and side-effects of antiretroviral therapy (ART), the practicability of taking it, and their beliefs about their ability to adhere to therapy all affect adherence [7–9].

Before prescribing ART (treatment initiation or switching), clinicians should assess:

- Patients’ readiness to take therapy;
- Their knowledge of its mode of action and efficacy, and perceptions of their personal need for ART;
- Concerns about taking ART or specific antiretroviral drugs including potential adverse effects;
- Concerns with possible adverse social consequences such as, for instance, disclosure or interference with lifestyle;
- Their confidence that they will be able to adhere to the medication (self-efficacy);
- Psychological or neurocognitive issues that could impact on adherence
- Socioeconomic factors which could impact on adherence including, but not limited to, poverty, housing, immigration status or domestic violence.

Community advocacy and peer support are helpful in supporting patient’s understanding and confidence around treatments and help the patient’s readiness and decision to start therapy. Community organisations in the UK have been instrumental in providing a range of patient information resources and peer support services including published and web based information.
materials, telephone advice lines, treatment advocates and peer support groups, working in collaboration with health care professionals. They are an important and essential adjunct to clinic based services and are helpful in addressing the issues discussed below.

A number of patient factors may affect adherence, adverse effects and treatment outcomes. Depression is significantly associated with low adherence [10,11] and some studies report an independent association between depression and mortality in people with HIV [12]. Adherence can be improved by treating depression [13], so all patients should be screened for depression before starting therapy, using simple screening tools such as the Arroll two-question quick screen [14]. Patients should also be screened for anxiety and for cognitive impairment.

Current problematic alcohol and recreational drug use are also associated with low adherence [15–17], though a history of injecting drug use, or even active use, is not necessarily so [18]. Patients should be asked about alcohol and recreational drug use and offered support to moderate or manage it if desired.

Conversely, adherence has been associated with positive experiences of quality of life such as having a meaningful life, feeling comfortable and well cared for, using time wisely, and taking time for important things [19]. Patient self-management skills and courses that teach them have been associated with both improved adherence and better clinical outcomes in a number of studies [20–22] and it may be helpful to patients to inform them of these and other psychological support options locally available, in line with the BPS/BHIVA Standards for psychological support for adults living with HIV [23].

A patient’s socioeconomic status has a more direct effect on adherence and other healthcare behaviours, than clinicians realise. For instance a US study found that poverty had a direct effect on adherence, largely due to food insufficiency [24]. A 2010 report on poverty in people with HIV in the UK found that one in six people with HIV was living in extreme poverty, in many cases due to unsettled immigration status [25]. Clinicians should be aware of patients’ socioeconomic status and refer to social support where necessary.

Clinicians should establish what level of involvement the patient would like and tailor their consultation style appropriately. Clinicians should also consider how to make information accessible and understandable to patients (e.g. with pictures, symbols, large print and different languages) [1] including linguistic and cultural issues. Youth is consistently associated with lower adherence to ART, loss to follow-up and other negative healthcare behaviours [26] and some studies have found an independent association between poorer adherence and attendance and female gender [27], so information and consultation style should be age- and gender-appropriate for the patient.

If there is a question about the patient’s capacity to make an informed decision, this should be assessed using the principles in the Mental Capacity Act 2005 [28].

Patients presenting at the clinic may be at different stages of readiness to take therapy [29] and clinicians’ first task is to assess their readiness, by means of open questions rather than closed, before supporting and furthering patients’ decisions on therapy. However if a patient presents in circumstances that necessitates starting ART immediately e.g. with certain AIDS diagnoses or very low CD4 counts then doctors should prescribe ART and provide support for the patient’s adherence, especially through the first few weeks. Recognising symptoms that patients attribute
to ART side effects might avoid loss of adherence and deterioration of trust in the patient-provider relationship [30,31].

Supporting patients requires good communication not just between clinician and patient but also between all health care staff involved with their care including those in their HIV services, their GP and any clinicians involved in management of co-morbid conditions. Patients should be offered copies of letters about them sent to their GP and other physicians. The advantages of HIV status disclosure to the patient’s GP, should be discussed and considered best practice, as several situations require consensual clinical decision making. A patient’s decision not to disclose their status to their GP should, however, always be respected, subject to the clinician’s duty to protect vulnerable individuals.

4. When to start

4.1 Chronic infection

4.1.1 Recommendations

- We recommend patients with chronic infection start ART if the CD4 count is ≤350 cells/µL [1A]: it is important not to delay treatment initiation if the CD4 cell count is close to this threshold.

The absolute risk of disease progression is significantly higher for a given CD4 count in older people (see Table 2.1), so consideration should be given to starting at higher CD4 counts in older persons. Evidence from cohort studies suggest that the risk of disease progression is significantly higher once the CD4 count falls below 350 cells/µL, so it is important not to delay unnecessarily the initiation of ART if the CD4 count is close to this threshold.

- We recommend patients with the following conditions start ART:
  - AIDS diagnosis (e.g. Kaposi’s sarcoma) irrespective of CD4 cell count [1A];
  - HIV-related co-morbidity including HIVAN [1C], ITP, [1C], symptomatic HIV-associated neurocognitive disorders irrespective of CD4 cell count [1C]
  - Co-infection with hepatitis B virus if the CD4 count is ≤500 cells/µL [1B] (see Section 8.2.2 Hepatitis B)
  - Co-infection with hepatitis C virus if the CD4 count is ≤500 cells/µL [1C] (Section 8.2.3 Hepatitis C)
  - Non-AIDS defining malignancies requiring immunosuppressive radiotherapy or chemotherapy [1C] (Section 8.3.2 When to start ART: non-AIDS-defining malignancies)

- We suggest patients with the following conditions start ART:
  - Co-infection with hepatitis B virus if the CD4 count is >500 cells/µL and treatment of hepatitis B is indicated [2B] (see Section 8.2.2 Hepatitis B)

Auditable measures

Proportion of patients with CD4 count <350 cells/µL not on ART

Proportion of patients with CD4 count ≥350 cells/µL and an indication to start ART not on ART

4.1.2 Rationale

To date there have been no published randomised trials that directly assess whether treatment-naive people with higher CD4 counts should initiate ART immediately rather than defer until the CD4 count falls to ≤350 cells/µL; whilst the START trial is addressing this question, results are not expected until 2015. Only one trial [1] has randomized people with a CD4 count > 350 cells/µL, but this used a comparator arm of delay of initiation of ARVs until the CD4 count has fallen.
below 250 cells/µL, and thus is likely to over-estimate the apparent benefits of immediate
treatment compared with starting at <350 cells/µL. There have been a number of observational
studies that have attempted to address this issue [2–9], which have produced conflicting
findings. Some of these studies have failed to take into account the lead-time between an
individual’s CD4 count falling below the threshold for treatment and the date of starting
treatment [8]; as this may introduce serious bias into treatment comparisons, these results do
not resolve the question whether it is better to start ART at higher CD4 cell counts.

Where studies have used methods that take the lead-time into account, the statistical methods
used are novel and different approaches have been used. The analyses reached substantially
different conclusions on the mortality benefits of early ART initiation in people with a CD4 count
>350 cells/µL, and particularly in those with CD4 count >500 cells/µL. Critically, none of these
methods are able fully to adjust for potential confounding, which might well be large in this
scenario and could create a bias that is in the same direction in all studies. Thus, we do not
believe that the evidence is currently sufficiently strong to recommend a change in guidelines.

Table 2.1 foot note: Predicted risk of AIDS if ART is deferred is taken from [10]. The predicted 6-month risk if ART is initiated is based on the assumption that the rate with immediate therapy initiation is one-third the rate without therapy initiation. This (probably conservative) value is based on considering evidence from multiple sources, including references [11–16]

4.2 Patients presenting with AIDS or a major infection

4.2.1 Recommendation

- We recommend patients presenting with an AIDS-defining infection, or with a serious bacterial infection and a CD4 count <200 cells/µL, start ART within two weeks of initiation of specific antimicrobial chemotherapy (1B).

Auditabe measure

Proportion of patients presenting with an AIDS defining infection or with a serious bacterial infection and a CD4 count <200 cells/µL started on ART within 2 weeks of initiation of specific antimicrobial chemotherapy

4.2.2 Rationale

This recommendation is largely based on the ACTG 5164 study that demonstrated fewer AIDS progressions/deaths and improved cost-effectiveness when ART was commenced within 14 days (median 12 days; IQR 9–13 days) compared to after completion of treatment for the acute infection (median 45 days; IQR 41–55 days) [1,2]. Those with tuberculosis as the primary infection were excluded from this study, and the majority of patients enrolled had pneumocystis pneumonia (PCP), followed by lesser proportions with cryptococcal meningitis and bacterial infections. The patients were well enough to give informed consent and to take oral medications, and therefore the findings may not be generalisable to those who are severely unwell or requiring intensive care. Previous observational data suggest a survival benefit for HIV positive patients who are started on ART whilst in the intensive care unit [3,4], but the data are insufficient to make a recommendation in this group [3,4]

There was no increase in the incidence of immune reconstitution disorders (IRD) or adverse events generally with early ART initiation in ACTG 5164 [1,5]. However those with intracranial opportunistic infections (OI) (such as cryptococcal meningitis [6]) may be more prone to severe IRDs with early ART initiation and increased observation of these patients may be warranted (though it is still recommended to initiate ART around two weeks after the commencement of OI therapy assuming the patient is stable). Those presenting with tuberculosis and malignancies are discussed in Section 8.
4.2.3 References

4.3 Treatment of primary HIV infection

4.3.1 Recommendations

• We recommend patients presenting with primary HIV infection and meeting any one of the following criteria start ART:

• Neurological involvement [1D]

• Any AIDS-defining illness [1A]

• Confirmed CD4 cell count <350 cells/µL (1C)

Auditable measure

Proportion of patients presenting with primary HIV infection and either neurological involvement or an AIDS defining illness or confirmed CD4 count <350 cells/µL started on ART

4.3.2 Rationale

The scientific rationale for treating with ART in primary HIV infection (PHI) is as follows:

1. Preservation of specific anti-HIV CD4+ T lymphocytes that would otherwise be destroyed by uncontrolled viral replication, the presences of which are associated with survival in untreated individuals [1].
2. Reduction in morbidity associated with high viraemia and profound CD4 depletion during acute infection [2–4].

3. Reduction in the enhanced risk of onward transmission of HIV associated with PHI [5–10].

Treatment of patients with primary HIV infection who present with AIDS-defining illnesses, neurological disease or a CD4 count of < 350 is consistent with the recommendations for patients with chronic infection. The rationale for treating patients with neurological disease is that ART may lead to regression of otherwise irreversible neurological disease (although there is no high quality evidence for this effect of treatment in primary infection). Data from the CASCADE collaboration [11] showed that in patients with primary infection who had at least one CD4 count of <350 cells µL in the first 6 months of infection had a significantly greater mortality than those whose CD4 counts remained above this threshold, which supports early treatment in patients with lower CD4 counts.

Multiple observational studies have shown encouraging but inconclusive results following short course ART initiated in PHI for individuals in whom ART would not otherwise be indicated [12,13]. There have been three RCTs comparing the role of interrupted ART initiated in PHI on time to reach CD4 <350 cells/µL or the need for initiation of lifelong ART [14–16]. Overall there was a modest benefit in terms of delaying the decline in CD4 count or time from seroconversion to requiring initiation of lifelong ART following a 48 [16] or 60 [15] week course of ART. A posthoc analysis from the SPARTAC trial [16] showed a non significant trend towards benefit in time to CD4 count <350 cells/µl when ART was initiated closer to the time of infection (HR 0.48 p = 0.09). This randomised study supported cohort studies in which a more rapid rate of CD4+ cell loss was seen in individuals presenting within 12 weeks of a negative HIV antibody test [17,18].

For this reason, we suggest that the following are discussed with those presenting with a very short test interval (≤12 weeks) in particular those with severe symptoms of seroconversion; such as rash, fever, weight loss, persistent lymphadenopathy, diarrhoea >4 days, malaise, headaches or laboratory evidence of acute HIV infection (e.g. as defined in SPARTAC [16]).

A 48 week course of ART showed a benefit in surrogate markers of HIV disease progression; delaying CD4 decline and lowering viral set point up to 60 weeks after stopping therapy; (there was no such benefit from 12 week ART); in those individuals presenting within 12 weeks of infection this effect was more marked; there is no clear evidence of long-term clinical benefit of ART in this setting.

No study has examined whether ART started during or soon after PHI should be continued long-term, but most clinicians would recommend that irrespective of indication to start ART, once initiated, it should be continued indefinitely. Discontinuation of ART in the context of treatment of primary HIV infection was not commonly associated with morbidity, however [15,16]

Initiation of a PI-based regimen is recommended if therapy is started prior to the availability of a genotype result based on the prevalence of transmitted rates of drug resistance in the UK [19].

There is no specific evidence to support the role of ART in PHI to prevent onward transmission of virus but there is little reason to consider that ART is any less effective in reducing infectivity at this time, so long as viral suppression has been achieved [20].
Patients with recently diagnosed primary HIV infection may be in a particularly vulnerable psychological state, and thus ill-prepared to commit to starting long-term treatment.

4.3.3 References

### 4.4. Treatment to reduce transmission

#### 4.4.1 Recommendations

- We recommend the evidence that treatment with ART lowers the risk of transmission is discussed with all patients, and an assessment of the current risk of transmission to others is made at the time of this discussion. (GPP)

- We recommend following discussion, if a patient with a CD4 count above 350 cell/µL wishes to start ART to reduce the risk of transmission to partners, this decision is respected and ART is started. (GPP)

#### Auditable measures

Record in patient’s notes of discussion, treatment with ART lowers risk of HIV transmission and an assessment of current risk of transmission.

The discussion should include the following:

The decision to start ART is the patient’s choice and must not be due to the pressure from partners or others.
ART lowers rather than eliminates the risk of transmission: other prevention strategies including male and female condoms continue to be recommended to address concerns of any residual risk of transmission.

For a patient with a CD4 count above 350 cells/µL, it is uncertain whether any benefits of immediate treatment to their own health will be outweighed by any harm.

Condoms both, male and female, continue to be recommended as protection from other sexually transmitted infections (STIs) and unplanned pregnancy.

There are risks associated to interrupting ART, once started, should generally continued indefinitely.

The evidence that ART lowers the risk of transmission mainly relates to vaginal sex. Although ART is highly likely to reduce the risk transmission for anal sex, the residual risk could be higher than seen in studies for vaginal sex. There are currently few data to inform this.

High and consistent adherence to ART is required to maintain viral suppression and minimise transmission risk.

Taking ART does not result in immediate complete viral suppression; it usually takes several months to achieve an undetectable viral load in blood.

The use of ART to reduce transmission risk is a particularly important consideration in sero-discordant heterosexual couples wishing to conceive and it is recommended that the HIV positive partner is on fully-suppressive ART.

### 4.4.2 Rationale

The potential effect of HIV treatment to reduce the risk of onward sexual transmission should be discussed with all patients as a part of safer sex messages in general. The discussion should include the HIV status of their partner(s) and whether ART is indicated for their own health.

This discussion should make clear that there is good evidence from one RCT (HPTN 052) [1] that ART treatment can markedly reduce (by 96%) the risk of transmission to HIV negative partners. This is supported by the secondary outcomes of another trial [2] that also found a marked reduction in transmission from partners taking ART (by 92%). It is important to note that only 3% of the couples in HPTN 052 were men who have sex with men (MSM) and the Partners in Prevention study was conducted entirely in heterosexual couples. The evidence base thus relates mainly to the risk of transmission for vaginal sex in heterosexual couples, it seems likely that a reduction in risk will also be seen for anal sex, but this is the subject of ongoing studies.

Prior to these randomized controlled studies the evidence base for treatment to reduce transmission was based on a number of cohort studies which found that transmission between heterosexual couples where the HIV-positive partner had an undetectable viral load on treatment was very rare or did not occur [3–7].

Viral suppression due to ART is usually as effective in reducing viral load in semen [8] and in the rectum [9] as in plasma. This suggests that in the absence of other facilitators of transmission such as STIs, ART would be expected to be as effective in reducing infectiousness in MSM and other populations as it is in heterosexuals. Indirect evidence comes from a study of MSM
attending HIV treatment services where ART was associated with a 96% reduction in HIV transmission [10].

Condoms should still be recommended, to protect from other sexually transmitted infections, and also to lower further any residual risk of transmission.

Patients should be informed that taking ART does not result in immediate viral suppression. Studies have shown that the mean time to suppression of viral load to <50 copies/ml in patients taking ART is about 90 days, and that a proportion may take nine months or more [11]. Patients should also be informed about the possibility of virological failure leading to transmission of HIV. Decisions on condom use and safer sex should always be based on a recent viral load test result and not on an assumption that taking ART implies non-infectiousness.

For sero-discordant heterosexual couples wishing to conceive irrespective of the method used for conception, the HIV positive partner will need to be on ART with an undetectable plasma viral load, regardless of his/her CD4 count or clinical status. This is likely to reduce the risk of transmission sufficiently to be the only risk reduction method some couples will want, but additional measures such as sperm washing, artificial insemination and potentially PrEP to the HIV negative partner have either been recommended in previous guidance [12] or are currently being assessed for couples wishing to address concerns of any residual risk of transmission.

Details of the use of ART to prevent mother to child transmission are covered in the pregnancy guidelines [13].

</tbody>
</table>

1. Abacavir is contraindicated if HLA B*5701 positive
2. Nevirapine is contra-indicated if baseline CD4 greater than 250/400 cells/µL in women/men.
3. Use recommended only if baseline viral load less than 100,000 copies/ml: rilpivirine as a third agent, abacavir + lamivudine as NRTI back bone

The presence or future risk of co-morbidities and potential adverse effects need to be considered in the choice of antiretroviral drugs in individual patients.

Summary auditable measures

Proportion of therapy naïve patients not starting ART containing 2 NRTIs and either a PI/r or a NNRTI or an INI (preferred or alternative agents)

Proportion of patients starting ART with either tenofovir/emtricitabine or abacavir/lamivudine as the NRTI backbone

Proportion of patients starting ART with either atazanavir/r, or darunavir/r, or efavirenz or raltegravir as the third agent.

Proportion of patients with undetectable VL <50 copies/ml at six months and at 12 months after starting ART

Proportion of patients who switch therapy in the first 6 and 12 months

Record in patient’s notes of HLA B5701 status prior to starting abacavir
5.2 Introduction

For the ‘which NRTI backbone’ and ‘which third agent’ questions evidence profiles and summary of findings tables were constructed to assess quality of evidence across pre-defined treatment outcomes (Appendix 3). Evidence from RCTs and systematic reviews was identified from a systematic literature review (Appendix 2). Outcomes were scored and ranked (critical, important, not important) by members of the writing committee. The following were ranked as critical outcomes: viral suppression at 48/96 weeks, protocol defined virological failure, drug resistance, quality of life, discontinuation for adverse events and grade 3/4 adverse events (overall), rash and ALT/AST elevation.

Treatments were compared and differences in critical outcomes assessed. Where there were differences, consensus opinion was sought to determine whether the difference in size of effect was above the threshold for clinical decision-making. If conflicting differences were detected, the balance of outcomes was based on consensus opinion of the committee.

A treatment was defined as preferred or alternative to indicate strong or conditional recommendations and the decision based on the assessment of critical outcomes and the balance of desirable and undesirable effects in a general ART naïve patient population. ‘Preferred’ indicates a strong recommendation that most clinicians and patients would want to follow unless there is a clear rationale not to do so. ‘Alternative’ indicates a conditional recommendation and is an acceptable treatment option for some patients and might in selected patients be the preferred option.

Factors including potential side effects, co-morbidities, patient preference, drug interactions need to be taken into account when selecting an ART regimen in individual patients and may include both preferred and alternative treatment options.

For guidance on assessment of patients prior to initiation of ART and monitoring of patients on ART the reader should consult the BHIVA guidelines for the routine investigation and monitoring of adult HIV-1-infected individuals 2011 (http://www.bhiva.org/Monitoring.aspx).

5.3 Which NRTI backbone

5.3.1 Recommendations

- We recommend therapy naïve patients start combination ART containing tenofovir and emtricitabine as the NRTI backbone. (1A)
- We suggest abacavir and lamivudine is an acceptable alternative NRTI backbone in therapy naïve patients who prior to starting ART have baseline viral load of ≤100,000 copies/ml (2A)
- Abacavir must not be used in patients who are HLAB*5701 positive. (1A)

5.3.2 Rationale

Three randomised controlled trials have compared tenofovir-emtricitabine (TDF-FTC) with abacavir-lamivudine (ABC-3TC) as the NRTI backbone in combination with: different third
agents: atazanavir/ritonavir (ATV/r) or efavirenz (EFV) [1–5], efavirenz [6–8] and lopinavir/ritonavir (LPV/r) [9].

Assessment of virological efficacy as a critical outcome was complicated by different definitions across the three studies. In our analysis for GRADE (see Appendix 3.1), there was no difference in rates of virological suppression at 48 weeks or 96 weeks but the analysis excluded the largest of the three trials (ACTG5202) and the quality of evidence for this outcome was assessed as low or very low. Assessment of the risk of protocol defined virological failure at 48 weeks favoured TDF-FTC (RR 0.76, 95% CI 0.53–1.07), the effect was not statistically significant and the heterogeneity in the analysis was relatively high (I² 46%). Assessment of protocol defined virological failure at 96 weeks showed a significant difference favouring TDF-FTC (RR 0.73, 95% CI 0.59–0.92). Data were only available from one study [3] for this analysis, however this was by far the largest of the three trials and the quality of evidence assessment for this outcome was rated as high. The difference in virological failure was assessed by the committee to be large enough to be above the clinical threshold for decision-making. The difference equates to a number needed to treat to prevent one case of virological failure of approximately 20 patients treated for one year.

The results of ACTG5202 [1–3] are complicated by the early termination of those individuals with a baseline viral load of >100,000 copies/ml at the recommendation of the data and safety monitoring board (DSMB) due to significantly inferior performance in those subjects receiving ABC-3TC. No difference in virological efficacy between the TDF-FTC and ABC-3TC arms was seen in those in the lower viral load stratum (baseline viral load <100,000 copies/ml). The subsequent 96-week analysis, after discontinuation of those subjects in the higher viral load stratum, may therefore underestimate the difference between the two backbones. HLA B5701 screening was not routine in ACTG5202 and this potentially may have influenced some of the safety endpoints, but appears not to have influenced the primary virological outcome. In the higher viral load strata the number of patients with suspected hypersensitivity reactions was equal between both arms and virological failure in these patients was infrequent.

With regard to the assessment of the other critical and important outcomes including drug resistance, discontinuation for adverse events and lipodystrophy, no difference was shown between TDF-FTC and ABC-3TC. No data were available to assess quality of life outcomes. For grade 3/4 adverse events (all) and grade 3/4 ALT/AST elevation there were trends that favoured TDF-FTC (see Appendix 3.1).

Although the rate of drug resistance was not different between the NRTI backbones, the number developing drug resistance was higher numerically in those receiving ABC-3TC, given the higher rate of virological failure.

The only outcome that significantly favoured ABC-3TC was bone mineral density but no difference in bone fractures was identified.

It is the view of the writing committee that given the favourable virological outcomes TDF-FTC compared to ABC-3TC and the lack of other significant differences in critical and important adverse event outcomes, TDF-FTC is recommended as the preferred NRTI backbone of choice. ABC-3TC is an acceptable alternative option in patients with a baseline viral load <100,000 copies/ml, but must only be used after ensuring a patient is HLA B*5701 negative.
When selecting a NRTI backbone, factors such as potential side effects, co-morbidities, patient preference and cost should also be considered. Observational studies have variably reported associations between ABC and cardiovascular disease [10–12], and TDF may cause renal disease [13]. These aspects will be discussed in more detail in Section 8. However, based on the balance of current evidence we suggest ABC is not used in individuals at high risk of cardiovascular disease (see Section 8.6 Cardiovascular disease) and TDF is not used in patients with stage 3-5 chronic kidney disease or at high risk of progression of CKD (see Section 8.5 Chronic kidney disease) if acceptable alternative ARVs are available.

### 5.3.4 Not recommended

The writing committee believes there is no routine role for other NRTI backbones in the treatment of ART-naïve patients. Zidovudine-lamivudine may be considered in certain specific circumstances e.g. pregnancy, (see BHIVA pregnancy guidelines [14]) but should not be given routinely due to the proven association with mitochondrial toxicity, particularly lipoatrophy with zidovudine. There is no place for the use of stavudine or didanosine containing regimens as initial therapy, due to the associations with significant mitochondrial and hepatic toxicities.

### 5.3.5 References

5.4 Which third agent?

5.4.1 Recommendations

- We recommend therapy-naïve patients start combination ART containing either atazanavir/ritonavir, or darunavir/ritonavir, or efavirenz, or raltegravir as the third agent. (1A)

- We suggest in therapy-naïve patients lopinavir/ritonavir and fosamprenavir/ritonavir are acceptable alternative protease inhibitors, and nevirapine and rilpivirine are acceptable alternative NNRTIs (2A).

- Nevirapine must only be used according to CD4 criteria and rilpivirine should only be used in patients with baseline viral load <100,000 copies/ml.

5.4.2 Rationale

The 2008 BHIVA guidelines recommended EFV as the preferred third agent in view of significantly better virological outcomes compared to LPV/r [1]. A similar outcome was subsequently reported in a smaller randomised study of patients commencing ART with advanced disease, as defined by a CD4 count of <200 cells/µL [2].

Since the 2008 guidelines, a number of comparative studies against either EFV or LPV/r have been reported, investigating alternative third agents.

Comparison with EFV: Atazanavir/ritonavir [3–9]; raltegravir [10–13]; rilpivirine [14–16]
Comparison with LPV/r: Atazanavir/ritonavir [17]; Darunavir/ritonavir [18–20]

For the current guidelines, evidence for agreed treatment outcomes for each potential third agent was compared to EFV, either directly or indirectly depending on the available evidence (Appendix 3).

ATV/r and raltegravir (RAL) have been compared directly with EFV in randomised control trials. For critical virological efficacy and safety outcomes, no differences were identified between EFV and either ATV/r or RAL. For these outcomes the quality of evidence was rated as high or moderate.

There was a difference in the rate of drug resistance favouring ATV/r (RR 3.94, 95% CI 2.37–6.56; \(P<0.00001\)) but the overall rate of emergent drug resistance was low for both treatments. This difference is a class effect and has previously been reported for other NNRTIs and PI/\(s\).

Differences were also identified in the rate of grade 3/4 CNS events and the rate of lipid abnormalities favouring both ATV/r and RAL. These differences may well influence choice between preferred third agents for individual patients.

There are no randomised controlled trials comparing DRV/r versus EFV directly. Thus an indirect comparison was undertaken using data from studies comparing DVR/r versus LPV/r [18–20] and LPV/r versus EFV [1,2] to assess outcomes between the two treatment options. Some differences between these studies were identified in terms of comparability and are outlined in Appendix 3. Overall these differences were judged to be insufficient to invalidate an indirect comparison between EFV and DRV/r.

Comparing DRV/r and LPV/r there were clinically significant differences in the critical outcomes virological suppression, discontinuation due to adverse events and serious adverse events in favour of DRV/r but no differences in the critical outcomes virological failure and drug resistance. Comparing EFV and LPV/r there was clinically significant differences in the critical outcomes virological failure and suppression at 96 weeks in favour of EFV but no differences in the critical outcomes drug resistance and discontinuation due to adverse events. In addition there were significant differences in some adverse events favouring EFV over LPV/r.

Rilpivirine (RPV) has been compared directly with EFV in randomised control trials [14–16]. With respect to critical virological outcomes there was no difference in virological suppression but there were differences in drug resistance (RR 0.38, 95% CI 0.20–0.72, \(P=0.003\)) and virological failure (RR 0.55, 95% CI 0.29–1.02, \(P=0.06\)), both in favour of EFV. Pooled analyses by the investigators of the two RCTs showed the risk of virological failure with RPV was highest in patients with a baseline viral load of >100,000 copies/ml [16]. For critical safety outcomes there was a difference in the proportion discontinuing for adverse events in favour of RPV (RR 2.29, 95% CI 1.15–4.57, \(P= 0.02\)) but no difference in serious adverse events. Rilpivirine also had better lipid profile outcomes.

In summary it is the view of the writing committee that EFV, given its performance across multiple well-controlled randomised trials and the wealth of clinical experience, should remain a preferred third agent. In addition because of similar critical treatment outcomes, it is the view of the committee that ATV/r, DRV/r and RAL are also recommended as preferred third agents.

For RPV versus EFV there were conflicting differences in critical outcomes. RPV was associated with fewer discontinuations for adverse events but the virological failure and resistance
outcomes favoured EFV. It was the opinion of the committee that on balance the virological and resistance outcomes outweighed the adverse event outcomes. For this reason RPV is recommended as an alternative third agent, but only in patients with baseline viral load <100,000 copies/ml.

As in the 2008 guidelines nevirapine (NVP) remains an alternative third agent, based on the associated CD4 cell count restrictions that limit its use plus the higher risk of moderate to severe rash/hepatitis and discontinuation for adverse events compared to other agents [21,22].

LPV/r is listed as an alternative third agent based on comparison of virological outcomes with EFV [1,2] and DRV/r [18,19], which have been previously discussed. Fosamprenavir/ritonavir is also listed as an alternative third agent as it has been shown to be non-inferior to LPV/r in terms of virological efficacy [23].

When selecting a third agent from either the preferred or alternative options, factors such as potential side effects, dosing requirements, dosing convenience, patient preference, co-morbidities, drug interactions and cost should be considered.

Neuropsychiatric side effects have commonly been reported in patients treated with EFV and patients with a history of psychiatric disorders appear to be at a greater risk of serious psychiatric adverse events [24]. In patients with a current or a history of psychiatric disorders including depression, anxiety and suicidal ideation caution should be exercised in prescribing EFV and strong consideration given to using an acceptable alternative third agent.

EFV may be used in pregnancy and the reader is directed to the BHIVA pregnancy guidelines 2012, for full discussion on this issue. Further discussion of choice of ART in selected populations is outlined in Section 8 ART in specific populations.

5.4.3 Not recommended

Saquinavir/ritonavir (SQV/r) is not listed as preferred or alternative options. SQV/r has been reported as non-inferior to LPV/r in terms of virological and safety outcomes [25] However a higher pill burden, the availability of alternative PI/rs and a recent update to the summary of product characteristics (SPC) requiring dose escalation and careful ECG monitoring due to its association with QT interval prolongation are the reasons SQV/r is no longer listed as a preferred or an alternative option in the treatment of ART-naïve patients with chronic infection.

The CCR5 antagonist maraviroc (MVC) and unboosted atazanavir are not licensed in Europe for initial ART and as such are not recommended.

### 5.5 Novel ART strategies

#### 5.5.1 Recommendation

- We recommend against the use of protease inhibitor monotherapy as initial therapy for treatment-naive patients. (1C)

#### 5.5.2 Rationale

Data on use of PI monotherapy as initial ART is limited. In one RCT comparing LPV/r versus LPV/r plus zidovudine and lamivudine, the use of PI monotherapy as initial ART was associated with lower rates of virological suppression at 48 weeks and with the emergence of PI mutations [1].
There were no significant differences in tolerability. For this reason PI monotherapy is not recommended as initial ART. However as with other novel strategies there may be specific circumstances where a rationale for its use may be made.

5.5.3 Reference

5.5.4 Recommendation

- We recommend against the use of protease inhibitor-based dual antiretroviral therapy with a single NRTI, NNRTI, CCR5 receptor antagonist, or integrase inhibitor as an initial therapy for treatment-naïve patients. (1C)

5.5.5 Rationale

A number of studies have assessed the use of protease inhibitor-based dual antiretroviral therapy as initial therapy in treatment-naïve patients. Many of these are either open label, not powered to demonstrate non-inferiority compared to triple therapy, single arm studies or have only been reported as conference abstracts.

The combination of a NNRTI with a PI/r has been shown to have similar virological efficacy compared to triple combination regimens in one study [1] There were no significant differences in time to either virological or regimen failure with a combination of LPV/r and EFV compared to either two NRTIs and EFV or two NRTIs and LPV/r. There was however an increased rate of drug resistance in the NRTI sparing arm, with the emergence of more NNRTI associated resistance mutations than the comparator arms. An increased rate of grade 3/4 toxicities was observed, predominantly LDL cholesterol and triglyceride elevations.

Comparison of a dual therapy regimen containing one NRTI with a PI/r (TDF and LPV/r vs two NRTIs and LPV/r) failed to demonstrate non-inferiority of the dual therapy arm compared to standard triple therapy combination [2].

The use of dual therapy with the CCR5-receptor antagonist maraviroc (MVC) in combination with a PI/r has been assessed in one RCT but was not designed to show non-inferiority [3] The comparative efficacy of the integrase inhibitor RAL plus a PI/r is being compared to standard triple therapy in several ongoing and/or unpublished studies [4–8]. Reports from one study [4,5] suggest similar rates of virological suppression at 48 and 96 weeks. However in a single arm study investigating RAL in combination with DRV/r, a significantly increased risk of virological failure with emergent integrase inhibitor resistance was seen in patients with baseline viral load $>100,000$ copies/ml compared to those with a baseline viral load $<100,000$ copies/ml [9]. Further data are required. There is a need to wait the results of ongoing randomised trials.
5.5.6 References

6. Supporting patients on therapy

6.1 Adherence

6.1.1 Interventions to increase adherence to treatment

6.1.1.1 Recommendations

We recommend adherence and potential barriers to it are assessed and discussed with the patient whenever ART is prescribed or dispensed (GPP).

We recommend adherence support should address both perceptual barriers (e.g. beliefs and preferences) and/or practical barriers (e.g. limitations in capacity and resources) to adherence (GPP).

Auditable measures

Record in patient’s notes of discussion and assessment of adherence and potential barriers to, prior to starting a new ART regimen and whilst on ART.

Record in patient’s notes of provision or offer of adherence support.

6.1.1.2 Rationale

Low adherence to ART is associated with drug resistance, progression to AIDS [1] and death [2–4]. Given the multiple adverse consequences of treatment failure (risk of disease progression, increase in complexity and costs of treatment and risk of HIV transmission) engaging patients in treatment decisions and the monitoring and support of adherence are of paramount importance [5] (see Section 3: Patient involvement in decision making).

Non-adherence is best understood as a variable behaviour with intentional and unintentional causes. Most people taking medication are non-adherent some of the time. Unintentional non-adherence is linked to limitations in capacity or resources that reduce the ability to adhere to the treatment as intended. Intentional non-adherence is the product of a decision informed by beliefs, emotions and preferences [6].

BHIVA recommendations on the monitoring of adherence to ART are available [7]. NICE has published detailed guidance on the assessment and support of adherence to medication in chronic diseases; key recommendations for adherence support are shown in Box 1 [8].
Box 1. Summary of NICE guidance on adherence support [8]

- A ‘no blame’ approach is important to facilitate open and honest discussion
- A patient’s motivation to start and continue with prescribed medication is influenced by the way in which they judge their personal need for medication (necessity beliefs), relative to their concerns about potential adverse effects. Delayed uptake and non-adherence are associated with doubts about personal need for ART and concerns about taking it [9,10]
- Interventions to support adherence should be individualised to address specific relevant perceptual and practical barriers. A three-step ‘Perceptions and Practicalities Approach’ (PAPA) [9] may be helpful:
  1. Identify and address any doubts about personal need for ART
  2. Identify and address specific concerns about taking ART
  3. Identify and address practical barriers to adherence
- Because evidence is inconclusive, only use interventions to overcome practical problems if there is a specific need. Interventions might include:
  o suggesting patients record their medicine-taking
  o encouraging patients to monitor their results
  o simplifying the dosing regimen
  o using a multi-compartment medicines system.
  o If side effects are a problem:
    ▪ discuss benefits, and long-term effects and options for dealing with side effects
    ▪ consider adjusting the dosage, switching to another combination or other strategies such as changing the dose timing or formulation.
- Patient’s experience of taking ART and their needs for adherence support may change over time.
  o Patients’ knowledge, understanding and concerns about medicines and the benefits they perceive should be reviewed regularly at agreed intervals.

6.1.2 Should the choice of first-line ART combination be affected by risk of non-adherence?

6.1.2.1 Recommendation

In patients where there is clinical concern that doses may be missed intermittently, there is insufficient evidence to recommend a PI/r over EFV-based regimens. However where there is a risk of frequent prolonged treatment interruptions EFV-based regimens may be associated with more frequent selection for drug resistance compared to ritonavir boosted PIs.

6.1.2.2 Rationale

Clinicians are poor at both predicting future adherence to ART in naïve subjects [11] and at detecting non-adherence during ART [12,13]. However in a case where a clinician or patient has concerns about a patient’s future adherence, should this influence the choice of first-line therapy?
The consequences of low adherence depend on drug pharmacokinetics, potency, fitness of resistant strains and genetic barrier to resistance [14]. Hence both the level and pattern of non-adherence must be considered.

Large randomized controlled trials of first-line therapy may not be able to inform this choice as subjects likely to be non-adherent are often excluded from such trials. On the other hand observational studies often select patients already established on ART [15,16] where the observed effects of non-adherence on treatment outcome are likely to differ from those in patients starting ART de novo. This selection bias may exclude those who have either experienced early virological failure, disease progression (or even death) or have defaulted from care. In addition most studies either predate the use of boosted PI regimens in first-line therapy [15,17] or include large numbers of patients on unboosted PI regimens.

Two different outcomes may be considered: virological suppression and selection of drug resistance.

**Effect of adherence on viral suppression**

There are no data from RCTs that directly address this question. Among subjects reporting <95% adherence in a RCT comparing LPV/r with once daily DRV/r, virological failure was more likely in the LPV/r arm [18].

Among initially virologically suppressed patients, adherence <95% is associated with an increased risk of failure [16] and very low adherence (<50%) results in virological rebound irrespective of regimen [5,16,19]. However virological suppression has been observed with only moderate adherence (50–75%) among patients on NNRTIs [5, 16,19] and virological failure has been reported to be significantly more likely among all patients on unboosted PI-based regimens where adherence was <95% [16]. However this finding may have been confounded by the once daily dosing in the EFV group. A further study [20] examined only patients with undetectable viraemia and found no difference in rates of virological rebound for patients on ritonavir boosted PIs v NNRTIs.

**Effect of adherence on selection of drug resistance**

The effect of level of non-adherence on selection of drug resistance varies by class. This was first described for unboosted PI regimens where moderate to high adherence was associated with increased risk of resistance [21]. The incidence of resistance in studies of boosted PI regimens is low [18,22–26] but is observed with adherence just below 80–95% [15,27]. In contrast, for first generation NNRTIs the selection for resistance has been associated with very low average adherence (<50%) [14,28]

**Effect of pattern of non-adherence**

The pattern of non-adherence may also be important. A number of small observational studies have examined short intermittent treatment interruptions (2–7 days) in patients with prolonged virological suppression. For EFV, cycles of two days off per week appeared no more likely to result in treatment failure than continuous therapy, as long the treatment interruption was not prolonged [29,30]. However cycles of 7 or 28-day treatment interruption resulted in failure of EFV and selection of resistance [31,32]. For ritonavir boosted PIs, one study found that average
adherence, rather than duration of treatment interruption, was associated with virological response [33].

### 6.1.3 Dosing frequency

A recent overview of systematic reviews of consumer-oriented medication interventions found that simplified dosing regimens improved adherence in the majority of studies in several reviews [34]. Another review of adherence interventions found that reducing dosing to once daily had some effect on adherence but no effect on treatment outcome was observed [35]. NICE [8] reviewed several RCTs of interventions to reduce dose frequency and found that adherence may increase with once daily dosing. For ART regimens, a meta-analysis of once versus twice daily ART regimens found that in the sub-group of treatment-naïve trials, once daily ART was associated with a significantly improved adherence and virological outcome [36].

Therefore once daily dosing is a reasonable intervention to reduce unintentional non-adherence to ART.

### 6.1.4 Fixed-dose combinations

In examining whether fixed-dose combination formulations (FDCs) of drugs improve adherence or treatment outcome, only studies comparing the same drugs with same dose frequency given as combination or separate pills were considered. No meta-analyses have been published on this subject for ART. A meta-analysis of nine RCTs and cohort studies in a range of diseases found the use of FDCs was associated with a significant reduction in the risk of non-adherence [36]. Gupta [37] reported a meta-analysis of cohort studies and found that use of FDCs for antihypertensives was associated with increased adherence but with no improvement on the control of blood pressure.

A retrospective study of a pharmacy database found no benefit in persistence on first-line ART for any FDC over separate agents [38]. A prospective observational study found that patients reported higher adherence over the preceding month (but not week) after switching from separate components to Atripla, however reporting bias cannot be excluded [39].

Patients may preferentially adhere less closely to one component of a regimen than others and FDCs may prevent this. While a minority of patients in one RCT of treatment strategies did report such 'differential' adherence, this was not associated with outcome for currently used first-line strategies [40].

Therefore FDCs can increase adherence. In patients with low adherence use of FDCs must be weighed against other treatment characteristics such as effectiveness, tolerability and resistance profile.

6.2 Pharmacology

More than for any other infection, patients receiving ART require their doctor to have a clear understanding of the basic principles of pharmacology in order to ensure effective and appropriate prescribing. This is especially the case in four therapeutic areas.

6.2.1 Drug interactions

6.2.1.1 Recommendations

- We recommend that potential adverse pharmacokinetic interactions between antiretroviral drugs and other concomitant medications are checked before administration (with tools such as www.hiv-druginteractions.org) (GPP)

Auditable measure

Record in patient’s notes of potential adverse pharmacokinetic interactions between antiretroviral drugs and other concomitant medications
6.2.1.2 Rationale

The importance of considering the potential for drug interactions in patients receiving ART cannot be overemphasised. Drug–drug interactions may involve positive or negative interactions between antiretroviral agents, or between these and drugs used to treat other coexistent conditions. A detailed list is beyond the remit of these guidelines but clinically important interactions to consider when co-administering with antiretroviral drugs include interactions with the following drugs: methadone, oral contraceptives, anti-epileptics, antidepressants, lipid-lowering agents, acid-reducing agents, certain antimicrobials (e.g. clarithromycin, minocycline and fluconazole), some anti-arrhythmics, tuberculosis therapy, anti-cancer drugs, immunosuppressants, phosphodiesterase inhibitors and anti-HCV therapies. Most of these interactions can be managed safely (i.e. with/without dosage modification, together with enhanced clinical vigilance) but in some cases (e.g. rifampicin and PIs, proton-pump inhibitors and atazanavir, and didanosine and HCV therapy) the nature of the interaction is such that co-administration must be avoided.

Importantly, patient education on the risks of drug interactions including over-the-counter or recreational drugs should be undertaken, and patients should be encouraged to check with pharmacies or their health care professionals before commencing any new drugs, including those prescribed in primary care.

Large surveys report that around 1 in 3-4 patients receiving antiretroviral therapy is at risk of a clinically significant drug interaction [1–6]. This suggests that safe management of HIV drug interactions is only possible if medication recording is complete, and if physicians are aware of the possibility that an interaction might exist. Incomplete or inaccurate medication recording has resulted from patient self-medication, between hospital and community health services [7] and within hospital settings particularly when multiple teams are involved, or when medical records are fragmented (e.g. with separate HIV case sheets) [8].

More worryingly, one survey in the UK reported that even when medication recording is complete, physicians were only able to correctly identify a third of clinically significant interactions involving HIV drugs [4]. In addition to HIV specialist and local drug information pharmacists, the University of Liverpool’s comprehensive drug interaction website (www.hiv-druginteractions.org) is an excellent and highly recommended resource for information relating to potential drug interactions. Additional information resources also include the electronic medicines compendium (www.medicines.org.uk/emc) and medical information departments of pharmaceutical companies.

Communication with GPs and other medical specialties involved in patient care is fundamental in minimising the risk of adverse drug–drug interactions. All clinic letters should carry as a standard header or footer advice to check for interactions, and links to resources, such as www.hiv-druginteractions.org, to address the potential for drug interactions.
6.2.2 Therapeutic drug monitoring (TDM)

6.2.2.1 Recommendation

• We recommend against the unselected use of TDM (GPP)

TDM may be of clinical value in specific populations (e.g. children, pregnant women) or selected clinical scenarios (e.g. malabsorption, drug interactions, suspected non adherence to therapy).

6.2.2.2 Rationale

TDM has been shown to be valuable in optimising the management of certain patients; however, the general utility of this test in patients receiving ART has been poorly assessed. With the marked improvement in efficacy and tolerability of modern anti-retroviral regimens, the role of TDM in clinical management has also evolved. A Cochrane review of randomized controlled trials [9] suggests little value when used unselectively. However, TDM may aid the management of vulnerable populations or complex clinical situations:

1. Monitoring adherence. Whilst detection of drug at therapeutic or even high plasma concentrations does not exclude low adherence, absence of measurable drug, or else very low levels of drug strongly suggests lack of medication intake, particularly in the absence of evidence of significant malabsorption. Here, TDM should rarely be interpreted in isolation, but rather integrated with virological rebound particularly in the absence of any resistance mutations, and other features in the history which suggest risk for low treatment adherence.

2. Optimising treatment in vulnerable patients (e.g. children, pregnant women and patients with extremes of BMI,) or else in specific clinical situations (e.g. liver and renal impairment, treatment failure, drug interactions both foreseen and unanticipated, malabsorption, suspected non adherence, and unlicensed once-daily dosing regimens). In these scenarios, the aim is to optimise dosing based either on known efficacy or toxicity cut-offs, or else to achieve the range of plasma concentrations encountered in patients without these factors, who have been recruited to PK studies at licensed treatment doses which are known to be both safe and efficacious.

3. Managing drug interactions (see above). Where the HIV drug has the potential to be adversely affected by another drug, and the combination is unavoidable, TDM may be used either to manage that interaction, or else discount a significant interaction in a particular patient.

4. Other situations. Knowledge of plasma drug concentrations may be clinically useful when evaluating whether there is scope for treatment simplification, or else confirming or refuting impaired drug absorption as a reason for virological failure.

More detailed recommendations for the use of TDM are available in the BHIVA Monitoring Guidelines 2011 [10]. As for all other investigations, it is essential that TDM is undertaken correctly, especially with regard to timing (undertaken when steady-state has been achieved). A consensus has been achieved for defining targets [11] for many ARVs. With many newer agents,
evidence for a defined minimum target for efficacy is either weak or lacking, and evidence for an upper toxicity cut-off for most ARVs is lacking.

6.2.3 Stopping therapy: pharmacological considerations

6.2.3.1 Recommendations

- We recommend patients stopping ART containing a NNRTI in combination with a NRTI backbone replace all drugs with a protease inhibitor (lopinavir/ritonavir) for four weeks. (1C)
- We recommend patients stopping a PI-containing regimen stop all drugs simultaneously and no replacement is required (1C)

Auditable measure

Proportion of patients with a undetectable viral load on ART who on stopping a regimen containing a NNRTI in combination with a NRTI backbone are switched to a ritonavir boosted PI for four weeks.

6.2.3.2 Rationale

In general, treatment interruptions are not recommended for most patients. Whatever the reason for stopping ART (e.g. drug toxicity, inter-current illness, after pregnancy, or patient choice), pharmacological issues must be considered in order for a clinician to give guidance. The half-life of each drug included in the regimen is critical. There is the potential for monotherapy or dual therapy if antiretroviral drugs with different half-lives are stopped simultaneously. NNRTI and NRTI resistance mutations have been detected following discontinuation of previously suppressive regimens [12] and may have the potential to affect the likelihood of viral re-suppression on restarting a NNRTI based ART regimen.

There is limited data on which to base recommendations for how to protect against development of resistance in the period immediately following treatment cessation. Several discontinuation strategies have been proposed [13], and choice is influenced by clinical considerations, patient wishes and pharmacological principles. Options include: (1) simultaneous stopping all drugs in a regimen containing drugs with similar half lives, (2) a staggered stop, discontinuing the drug with the longest half life first in a regimen containing drugs with short and long half lives; or (3) replacing all drugs with a drug with a short half life and high genetic barrier to resistance (i.e. a protease inhibitor). There is no randomised comparison of these three strategies. However in one study lower numbers of emergent resistance mutations was seen in patients switching to a PI compared to those undertaking a simultaneous or staggered stop [12]. Therapeutic plasma concentrations of EFV can also be detected up to three weeks after stopping the drug in some patients and thus a staggered stop of one week may potentially be inadequate to prevent emergence of NNRTI mutations [14]. The optimal duration of replacement with a PI is not known, but four weeks is probably advisable.
6.2.4 Switching therapy: pharmacological considerations

6.2.4.1 Recommendations

Data on how to switch away from EFV to an alternative ‘third’ agent are either non-existent, or of low or very low quality. Based on pharmacological principles, there is little rationale for any strategy other than straightforward substitution when switching to a PI/r, or RAL. Pharmacokinetic studies show that straightforward substitution with ETV and RPV may result in slightly lower concentrations of either drug for a short period following switching, but limited virological data suggest that risk of virological failure with this strategy is low. Different strategies for switching to NVP have been proposed, but no comparative data are available to guide the choice of strategy. Limited data suggest that the dose of MVC should be doubled in the week following switching (unless given together with a PI/r).

If switching away from EFV is undertaken when viral load is likely to still be detectable (e.g. as a result of CNS intolerance within the first few weeks of starting EFV), substitution with a PI/r in preference to a within-class switch is advised.

6.2.4.2 Rationale

Switching a component of an ART regimen is frequently considered in patients to manage drug side effects or address adherence issues. ARVs which either induce or inhibit drug metabolising enzymes have the potential to affect the plasma concentrations of the new agent. This applies in particular to switching away from NNRTIs. Induction of drug metabolising enzymes by EFV is likely to persist for a period beyond drug cessation. Consideration should also be taken of whether or not viral load is maximally suppressed when planning how to switch away from EFV to an alternative agent. Broadly, strategies for switching from EFV to an alternative ‘third’ agent may be summarized as follows:

Efavirenz to nevirapine:

A pharmacokinetic study performed in HIV positive individuals suggested that patients changing from EFV to NVP should commence on 200 mg twice a day to ensure therapeutic plasma concentrations and potentially avoid selection of resistance to NVP [15]. However no patient in the NVP lead-in group experienced virological failure in the 3 month follow up period. Switching without dose escalation is in direct contrast with the information in the Viramune SPC which advises the administration of a NVP lead-in dose (200 mg once daily for two weeks) when starting NVP [16] as this has been shown to decrease the frequency of rash.

In ART experienced patients who are virologically suppressed with an undetectable plasma HIV RNA level (<50 copies/ml), the risk of hypersensitivity and/or hepatotoxicity on switching to NVP is not increased in patients with higher CD4 counts (above the gender specific CD4 count thresholds) [17] In ART experienced patients with detectable plasma HIV RNA levels, a switch to NVP is not advised.

Furthermore the need to minimise any window for developing resistance is greatest in patients who discontinue EFV early on when virological suppression has not yet been achieved. The latter scenario is made more complex when enzyme induction has not yet been fully achieved, and if doubt exists, alternative choices to switch to should be considered.
Efavirenz to etravirine:

Steady-state (14 days following the switch) etravirine (ETV) pharmacokinetic parameters are lowered by previous EFV intake in the case of both once- (Cmin was lowered by 33%) and twice-daily (Cmin was lowered by 37%) administration. However, ETV concentrations have been shown to increase over time following the switch and in patients with undetectable viral loads switching from EFV to ETV, standard doses of ETV can be commenced [18]. No data are to date available on what strategy to adopt in patients with active viral replication.

Efavirenz to rilpivirine:

Concentrations of RPV are lowered by previous EFV administration. However, 28 days after the switch, they returned to levels comparable with those when RPV was administered without prior EFV treatment, except for a 25% lower Cmin. Therefore, in patients with undetectable viral loads switching from EFV to RPV, standard doses of RPV can be commenced [19]. No data is to date available on what strategy to adopt in patients with active viral replication.

Efavirenz to a PI/r:

Because of the strong inhibitory effect of ritonavir on CYP450 3A4, it is unlikely to require a modification of the PI/r dose when switching from EFV to a PI/r. Formal pharmacokinetic data are unavailable. TDM data were presented on ATV/r and showed that after stopping EFV, ATV concentrations were above the suggested minimum effective concentration in all studied subjects [20].

Efavirenz to raltegravir:

Although formal pharmacokinetic data are not available, switching EFV to RAL should not lead to clinical significant consequences, as co-administration of EFV with RAL led to a moderate to weak reduction in RAL Cmin (21%) [21] and this may persist for two to four weeks after the switch but the degree of this reduction is unlikely to be clinically meaningful.

Efavirenz to maraviroc:

A formal pharmacokinetic study in HIV positive individuals showed that the induction effect of EFV necessitated an increase in MVC dose to 600 mg twice daily for one week following the switch [22]. Maraviroc 300 mg twice daily (standard dose) seems to be safe after this period. Although the absence of data, when switching from EFV to MVC plus a PI/r, it is likely that a dose of 150 mg twice daily is safe from the first day after the switch. Whether it is advisable to use MVC 150 mg once daily in this context or for how long a twice-daily dose should be used after the switch remains unknown.

6.3 Switching ART in virological suppression

6.3.1 Introduction

In patients on fully viral suppressed regimens, switching individual components of the ART combination regimen is frequently considered for several reasons including: management of ARV drug toxicity or intolerance, desire for once daily dosing and reduced pill burden, management of potential drug–drug interactions, patient preference and cost [1]. Guidance on the management of the drug toxicity of individual ARVs is not within the scope of these guidelines. Guidance on interventions to support adherence including once daily dosing and fixed-dose combinations is addressed in Section 6.1 Adherence and pharmacological considerations on switching ARVs is discussed in Section 6.2.4 Switching therapy: pharmacological considerations.

Switching individual components of an ART regimen may well improve adherence and tolerability, but should not be at the cost of virological efficacy. The following guidance concerns the impact on virological efficacy of either switching the third agent or the NRTI backbone in a combination ART regimen or simplifying to boosted PI monotherapy. Evidence from a systematic literature review (Appendix 2) was evaluated, the impact on critical treatment outcomes of different switching strategies assessed. Critical outcomes included virological suppression at 48 weeks, virological failure and discontinuation from grade 3/4 events.
6.3.2. Switching ARVs in combination ART

6.3.2.1 Recommendations

- We recommend in patients on suppressive ART regimens, consideration is given to differences in side effect profile, drug–drug interactions and drug resistance patterns before switching any ARV component. (GPP)

- We recommend in patients with prior NRTI resistance mutations, against switching a ritonavir boosted PI to either a NNRTI or an INI as the third agent. (1B)

**Auditable measure**

Number of patients with an undetectable VL on current regimen and documented prior NRTI resistance who have switched a PI/r to either a NNRTI or an INI as the third agent

6.3.2.2 Rationale

Within class switches are usually undertaken to improve ARV tolerability. The available evidence for current recommended third agents is limited but switching PI/rs or NNRTIs in virologically suppressed patients has in a small number of studies not been associated with loss of virological efficacy [2–4]. Consideration should however be given to differences in side effect profiles, drug–drug interactions and food effect and for switching between different PIs to the prior history of major PI mutations, as this may potentially have an adverse effect on the virological efficacy of the new PI/r.

For NRTIs recent studies have mainly evaluated switching from a thymidine analogue to either TDF or ABC to manage patients with lipoatrophy or have investigated switching to one of two available NRTI fixed-dose combinations (TDF and FTC or ABC and 3TC). If screening for HLA B5701 positivity is undertaken prior to a switch to ABC, then similar virological efficacy is seen in patients switched to ABC-3TC FDC compared to a switch to TDF-FTC FDC [5]. In general, in the absence of prior resistance mutations, switching within class should result in maintaining virological suppression.

Several RCTs have assessed switching between classes (PI to a NNRTI and PI to an INI) in patients who are virologically suppressed. A meta-analysis of six trials showed non-inferiority in maintenance of virological suppression when switching from a PI (both ritonavir boosted and unboosted) to NVP compared to continuing the PI but was associated with more discontinuations due to liver toxicity [6]. Previous treatment failure on a NRTI containing regimen has been associated with an increased risk of virological failure when switching from a PI to a NNRTI based regimen [7]. A recent cohort analysis showed similar rates of virological failure at 12 months in patients switching from a first-line PI/r to either EFV or NVP compared to continuing on the PI/r. [8]. If switching to NVP, consideration should be given to the risk of hypersensitivity reactions and hepatotoxicity. Similar rates have been reported in virologically suppressed compared to ART naïve patients stratified for CD4 count and gender [9,10]. For patients without prior NRTI or NNRTI resistance mutations switching from a PI/r to any of the current licensed NNRTIs is likely to maintain virological efficacy and choice of NNRTI will depend on side effect profile, tolerability and patient preference.
Switching from a PI/r to the integrase inhibitor, RAL, in virologically suppressed patients has been evaluated in three RCTs. Two studies have shown that a prior history of NRTI resistance mutations increases the risk of subsequent virological failure on switching compared to continuing on a PI/r [11,12]. This association was not seen in a third trial [13]. However it is not surprising that switching from an ARV with a high genetic barrier to one with a low genetic barrier to resistance may potentially increase the risk of virological failure if the activity of the NRTI backbone has been compromised by prior NRTI resistance.

There is limited data on switching from a NNRTI to an alternative third agent in virologically suppressed patients however consideration must be given to prior treatment history and potential PK interactions. The latter is discussed in more detail in Section 6.2.4 Switching therapy: pharmacological considerations.

### 6.3.2.3 References

6.3.3. Protease inhibitor monotherapy

6.3.3.1 Recommendation

- We recommend continuing standard combination ART as the maintenance strategy in virologically suppressed patients (1C). There is insufficient data to recommend PI/r monotherapy in this clinical situation.

Auditable measure

Number of patients on PI/r monotherapy as ART maintenance strategy in virologically suppressed patients and record of rationale

6.3.3.2 Rationale

For the assessment and evaluation of evidence, GRADE tables were constructed (Appendix 3). Virological suppression, drug resistance and serious adverse events were defined as critical outcomes. From the systematic literature review (Appendix 2) 10 RCTs were identified, investigating the use of either LPV/r or DRV/r in stable, virologically suppressed patients without active hepatitis B co-infection [1–14].

Assessment of virological suppression showed significantly fewer patients on PI monotherapy maintaining virological suppression compared to those continuing on standard combination ART (RR 0.95 95% CI 0.9,0.99), although the difference was small. A similar result has previously been reported in a meta-analysis [15]. Viral load rebound is usually at low level, and is easily reversed by re-introduction of NRTIs. The long-term consequences of this viral rebound and re-suppression are unknown. There were no differences in the frequency of emergence of viral resistance, or of serious adverse events, though few patients developed drug resistance and thus the confidence in the estimate of this effect is low. One potential concern is the development of CNS disease in patients on PI monotherapy [6,11] however we did not identify a difference in this outcome though the quality of the evidence is low. Further data are required.

Overall there is no significant clinical benefit of PI monotherapy compared to standard combination ART, which might offset the disadvantage of a lower rate of viral suppression with
PI monotherapy. For this reason PI monotherapy should not be used in unselected patient populations for maintaining virological suppression where standard ART is an acceptable alternative. There may be potential benefits of PI monotherapy, in terms of drug resistance, long-term drug toxicity and cost [16] but further data are required. The ongoing ‘Protease Inhibitor monotherapy versus Ongoing Triple therapy in the long-term management of HIV infection’ (PIVOT) trial has been designed to address these issues [17]. The primary end point is drug resistance.

We recognise that PI monotherapy may well be an acceptable option in some specific patient populations but there are few data to provide recommendations. Clinicians, might consider PI monotherapy in patients who are unable to tolerate NRTIs due to toxicities or as a short term measure to manage or bridge complex clinical scenarios (e.g. stopping certain NNRTI containing regimens or managing toxicity overdose or acute illness) Where PI monotherapy is considered, DRV/r (dosed once or twice daily) or LPV/r (dosed twice daily) should be used. ATV/r monotherapy is not recommended as it has been associated with higher rates of virological failure [18,19]. PI monotherapy is not recommended in patients with active hepatitis B co-infection.

6.3.3.3 References

6.4 Stopping therapy

6.4.1 Recommendation

- We recommend against treatment interruption or intermittent therapy in patients stable on a virally suppressive ART regimen (1A)

Auditable measure

Proportion of patients with a CD4 count <350 cells/µL not on ART

6.4.2 Rationale

Several RCTs have investigated the efficacy of CD4 count guided intermittent therapy as a potential strategy to reduce long-term risk of drug toxicity and drug resistance [1–4]. In the
largest of these, patients were randomised to either CD4 count guided intermittent therapy (stopping ART once CD4 count above 350 cells/µL, restarting when CD4 count falls to 250 cells/µL) compared to a continuous ART [1]. The trial showed intermittent therapy was associated with a significantly higher rate of opportunistic disease and all cause mortality and a higher rate of major cardiovascular, renal or hepatic disease. The effect was seen at all CD4 count levels. The study showed for the first time that continuous ART with virological suppression is associated with a reduction in the risk of non-AIDS co-morbidities and all cause mortality as well as HIV disease progression. For this reason treatment interruption or intermittent therapy is not recommended.

Once ART has been started in a patient with HIV infection, it should be continued. Temporary interruptions of 1–2 days can usually be managed and are unlikely to be associated with adverse outcomes. Longer interruptions of ART should only be considered in exceptional circumstances. These may include:

- After pregnancy, in women who have taken ART during pregnancy to prevent mother-to-child transmission, but do not otherwise require treatment.
- After early initiation of ART (CD4 counts >500 cells/µL) e.g. when started to reduce infectiousness.
- Severe drug toxicity e.g. hepatotoxicity
- Severe psychological distress

Guidance on pharmacokinetic considerations when stopping ART is contained in Section 6.2.3 Stopping therapy: pharmacological considerations.

7. Managing virological failure

7.1 Introduction

For detailed guidance on HIV viral load, resistance and genotypism testing, the reader should consult the BHIVA monitoring guidelines (www.bhiva.org).

The following recommendations concern the management of patients experiencing virological failure on ART. Patient populations at the time of virological failure will include those with no or limited HIV drug resistance through to those with three class failure and either no or limited treatment options. For the assessment and evaluation of evidence, priority questions were agreed and outcomes were ranked (critical, important, and not important) by members of the writing committee. For patients with no or limited HIV drug resistance the following were ranked as critical outcomes: viral suppression <50 copies/ml at 48 weeks, development of resistance, discontinuation rates for clinical and laboratory AE; for patients with three class failure/few therapeutic options: clinical progression, median CD4 count change at 48 weeks, development of new resistance. Treatments were compared where data was available and differences in outcomes assessed. Details of the search strategy and literature review are contained in Appendix 2.

In the UK, the virological failure rate on current first-line regimen in 2008-2009 was approximately 10% at one year [1]. The options for switch depend on the most recent and past ARV treatments as well as current and archived resistance results. As genotypic testing in ARV naive is now performed routinely and is recommended practice, detection of resistance at virological failure is rarely a result of transmitted drug resistance and failure to adapt first-line treatment [2,3].

The General principles for the management of patients experiencing virological failure are outlined in boxes 1 and 2 as good practice points. Details of typical patterns of HIV drug resistance found in patients with a history of or presenting with virological failure is outlined in box 3. For guidance on HIV viral load, drug resistance and tropism testing the reader should consult the BHIVA guidelines for the routine investigation and monitoring of adult HIV-1-infected individuals 2011 [4](www.bhiva.org/Monitoring.aspx).

Summary auditable measures

Record in patient’s notes of resistance result at ART initiation (if available) and at first viral load >400 copies/ml and/or before switch

Record in patient’s notes of adherence assessment and tolerability/toxicity to ART in patients’ experiencing virological failure or repeated viral blips.

Number of patients experiencing virological failure on current ART regimen

Proportion of patients experiencing virological failure switched to a new suppressive regimen within 6 months

Proportion of patients on ART with prior documented HIV drug resistance with VL <50 copies/ml
Record of patients with three class virological failure with or without three class resistance referred/discussed in MDT with expert advice.

7.2 Blips, low level viraemia and virological failure

7.2.1 Recommendations

- In patients on ART:
  - A single viral load of 50–400 copies/ml preceded and followed by an undetectable viral load is usually not a cause for clinical concern (GPP)
  - We recommend a single viral load >400 copies/ml is investigated further, as it is indicative of virological failure (1C)
  - We recommend in the context of repeated viral blips, resistance testing is attempted (1D)

7.2.2 Rationale

Blips: Optimal HIV control is ordinarily reflected by complete viral suppression with an undetectable viral load. A virological blip is variably defined but for the purposes of these guidelines the definition that has been adopted is a detectable viral load of <400 copies/ml, which is preceded and followed by an undetectable result without any change of therapy. Blips are frequent and represent random variation around a mean undetectable viral load [5–7]. Many patients have at least one at some time [8] when they are not predictive of virological failure or associated with emergent resistance in most studies [5,9,10]. Viral load assay variation and laboratory processing artefacts account for many blips (i.e. no ‘true’ increase in viral replication), which partly explains why blips do not appear to compromise long-term outcomes [9,11–12]. However, those with sustained low-level increases in viral load run a higher risk of virological failure. Most blips are low-level (median magnitude 79 copies/ml in one study [range 51-201]) and short lived (median 2.5 days [range 2–11.5]) [7]. In a retrospective study, 28.6% of patients, experienced VL increases from 50-500 copies/ml over 8 years; 71% of these were blips [8].

Review and reiteration of the importance of full adherence, as well as looking for any tolerability/toxicity issues, drug–drug/food interactions, and archived resistance should take place. However, blips do not appear to be related to inter-current illness, vaccination, baseline CD4/VL, duration of preceding suppression or level of adherence [7,14,15]. Therefore, it is the recommendation of the writing committee that a viral load result of 50–400 copies/ml preceded and followed by an undetectable viral load should not be a cause of clinical concern. In the context of repeated blips, it may then be useful to test for resistance [16,17].

Low level viraemia is defined as a repeatedly detectable but low level of viraemia (LLV) over a sustained period of time. For the purposes of these guidelines, <400 copies/ml is used although it is recognised that some patients have viral loads up to 1000 copies/ml without development of resistance and with therapeutic drug levels. LLV is observed in up to 8% of individuals [18] and is associated with an increased risk of virological rebound (>400 copies/ml) [6,19]. The likelihood
of resuppression after LLV is greater for lower magnitudes of viraemia: 41% after two consecutive viral loads of >50 copies/ml compared with 12% after two VLs >200 copies/ml [20]. LLV is associated with resistance (37% in one study [21]) that may be associated with LLV magnitude; in one analysis, maximum viral load was higher in those with who developed resistance (368 vs. 143 copies/ml; P=0.008). LLV is also associated with immune activation [10]. Low-level antigenic exposure differentially affects T-cell activation and HIV specific T cell response. In cohort studies [19] and clinical trials [21] patients on PI/r-based ART are more likely to experience detectable viraemia than those on an NNRTI. In the absence of clear data, the committee believes LLV on a low genetic barrier regimen warrants prompt regimen change. This is especially true where ART combination without a boosted PI is being used [22,23]. Further evaluation should follow as for that listed in Box 1.

Failure is defined as failure to achieve a viral load of <50 copies/ml 6 months after commencing ART or following viral suppression to <50 copies/ml a viral load rebound to >400 copies/ml on two consecutive occasions. In the UK approximately 18% of those achieving an undetectable viral load in 2008-2009 experienced viral load rebound. In the same database, among drug experienced patients the overall prevalence of resistance was 44% in 2007[1]. Confirmation of virological failure at any stage should lead to the practice set out in Box 1.

**Box 1: Best practice for the management of patients with virological failure**

- Factors affecting adherence and drug exposure including tolerability/toxicity issues, drug–drug/food interactions, ARV potency, significant renal/liver disease, and mental health/drug dependency problems are evaluated
- Resistance testing is performed while on failing therapy or within four weeks of discontinuation
- Past ART and resistance tests are reviewed for archived mutations
- Tropism testing is performed if maraviroc is being considered
- Intensification with an additional active ARV is not recommended
- Once virologic failure is confirmed and a resistance result available, the regimen is changed as soon as possible to avoid accumulation of resistance mutations

The choice of the new ART regimen will primarily depend on the results of resistance testing and the patient’s preference. Additional considerations include the results of tropism and HLAB57 testing, drug–drug/food interactions, co-morbidities and future therapy options. The goal of the new combination is to re-establish a VL <50 copies/ml.

**Box 2: Best practice for the management of patients with three class virological failure**

- In patients with ongoing viraemia and with few options to construct a fully suppressive regimen, referral for specialist advice and/or discussion in an MDT ‘virtual’ clinic
- Include at least two and preferably three fully active agents with at least one active PI/r(e.g.DRV/r) and one agent with a novel mechanism of action (CCR5 antagonist/integrase or fusion inhibitor)
- Treatment interruption is not recommended
7.3 Patients with no or limited drug resistance

**7.3.1 Recommendations**

- We recommend patients experiencing virological failure on first-line ART with WT virus at baseline and without emergent resistance mutations at failure, switch to a PI/r-based combination ART regimen. (1C)

- We recommend patients experiencing virological failure on first-line ART with WT virus at baseline and limited emergent resistance mutations (including two-class NRTI/NNRTI) at failure, switch to a new PI/r-based regimen with the addition of at least one preferably two active drugs (1C)

- We recommend patients experiencing virological failure on first-line PI/r – two NRTI based regimen with major protease mutations, switch to a new active PI/r with the addition of at least one, preferably two active agents of which one has a novel mechanism of action (1C)

- We recommend against switching a PI/r to raltegravir or a NNRTI as the third agent in patients with historical or existing RT mutations associated with NRTI resistance or past virological failure on NRTIs (1B)

**7.3.2 Rationale**

**7.3.2.1 First-line treatment failure with no resistance**

A significant minority of patients have WT virus despite failing on therapy [24–30]. Failure here is usually attributable to poor treatment adherence with drug levels that are both insufficient to maintain viral load suppression and inadequate to select out viral mutations associated with

drug resistance detectable on standard tests. Factors affecting adherence such as tolerability/toxicity issues, regimen convenience, drug-food interactions, and mental health/drug dependency problems should be fully evaluated and where possible corrected before initiation of the new regimen. Additional adherence support should be considered and careful discussion with the patient take place. TDM may be of benefit in individual patients in confirming low/absent therapeutic drug levels and enabling discussion with the patient.

A priority question the writing committee addressed was whether patients failing an NNRTI-based ART without detectable resistance should receive a PI/r-based regimen.

The absence of detectable resistance mutations does not exclude the presence of mutations in minor virus populations, especially with the NNRTIs [9–11]. This may lead to subsequent failure if the same first-line drugs, or drugs in the same class, are prescribed [31,32]. Testing for minority resistance is a specialist test and expert interpretation by a virologist is essential. There is no indication for routine minority species testing in patients failing with WT virus on therapy.

The recommendation of the writing committee is that, following NNRTI/two NRTIs virological failure when no resistance mutations exist, a switch to a PI/r-based regimen should lead to virological suppression and is unlikely to lead to emergent resistance. The decision as to whether or not to restart the same NNRTI-based combination or switch to another NNRTI, RAL or MVC (where CCR5 tropism has been confirmed) has to be individualised to the patient, their past history of virological failure, and to whether further switches in the combination are occurring.

No supportive data exists for management of virological failure when this has developed on first-line therapy with RAL/two NRTIs but the general principles set out for NNRTI-based failure would still apply. However, the high genetic barrier of PI/rs reduces the risk of low-level resistance developing.

### 7.3.2.2 First-line treatment failure with NNRTI resistance

Up to two-thirds of virologically failing patients harbour viruses with NNRTI and half NRTI mutations at 48 weeks [27–30, 33]: with increasing time, there will be accumulation of resistance mutations that may compromise second-line regimens [34]. Although potential options for second-line therapy after failure on an NNRTI-containing include, RAL, ETV and MVC (RPV is not licensed for this indication), evidence supports the use of a PI/r. A switch to any PI/r-based regimen should lead to virological suppression and is unlikely to lead to further emergent resistance and should be considered whenever possible. Where NRTI resistance has been documented or likely, these should be replaced and new active NRTIs or other ARVs should be incorporated. There are no direct comparisons of the boosted PIs in second-line treatment after first-line failure on an NNRTI-based regimen and choice would be individualised to the patient. Sequencing from an EFV or NVP-based regimen to ETV is not recommended [35] although remains an option when switched as part of a new combination when only K103N is present. Switching to RAL or MVC with two active NRTIs is an option but is also not recommended in a patient with historical or existing RT mutations/prior NRTI virological failure [36].
7.3.2.3 First-line treatment failure on a PI/r-based two NRTI regimen with or without PI resistance

Less than 1% of patients harbour viruses with primary PI mutations and 10–20% NRTI mutations at 48 weeks, with 75% having WT virus [27–29, 37–39]. There is currently limited data regarding the efficacy of switching to another PI/r, NNRTI, MVC, or RAL-based regimen and again the decision is individualised to the patient. However, switching to RAL, MVC, or a NNRTI in a patient with historical or existing RT mutations is not recommended because of an increased risk of virological failure and further emergence of resistance [36]. By contrast, because of the high genetic barrier of PI/rs, sequencing to a regimen that includes a new PI/r is unlikely to lead to further emergent resistance and is recommended. Where PI/r mutations exist, DRV/r is the preferred agent unless resistance is likely.

7.3.2.4 First-line treatment failure with INI based resistance

Up to one half harbour viruses with primary integrase mutations and 25% NRTI mutations at 48 weeks: approximately half have WT virus [26,33,37,40]. Again, there are no data supporting a switch to a PI/r, NNRTI, or MVC but sequencing to a new regimen which includes a PI/r is unlikely to lead to further emergent resistance and is recommended. Switching to an NNRTI or MVC with two active NRTIs is an option but is also not recommended in a patient with historical or existing RT mutations/prior NRTI virological failure. Patients experiencing virological failure on RAL should switch to a new regimen as soon as possible to reduce the risk of accumulating resistance mutations which may affect susceptibility to newer INIs such as dolutegravir.

7.4 Patients with triple-class (NNRTI, NRTI, PI) virological failure with or without triple-class resistance

7.4.1 Recommendations

- We recommend patients with persistent viraemia and with limited options to construct a fully suppressive regimen are discussed/referred for expert advice (or through virtual clinic referral). [GPP]

- We recommend patients with triple-class resistance switch to a new ART regimen containing at least two and preferably three fully active agents with at least one active PI/r such as darunavir/ritonavir or tipranavir/ritonavir and one agent with a novel mechanism (CCR5 receptor antagonist or integrase/fusion inhibitor) with etravirine an option based on viral susceptibility [1C]

7.4.2 Rationale

Risk of development of triple class virological failure is relatively low at around 9% at nine years from start of ART [41]. Until the last few years, limited treatment options have been available for people with HIV who have had virological failure with the three original classes of HIV antiretroviral drugs (triple-class virological failure) of whom many have developed triple-class resistance. Most of these patients have received suboptimal ARV treatment, often from the pre-HAART era, or have been adhered poorly to multiple regimens and have accumulated resistance. However, with the introduction of several new agents active against resistant virus, many of
which have novel sites of action, the potential for virological control akin to that achieved with naïve patients has now become a probability [42,43].

Consequent to more active ARVs and improved strategies of management, there has been substantial improvement in the proportion of people who had virological response after triple-class virological failure between 2000 and 2009 [44]. However, despite improvements in treatments, viral loads cannot be suppressed for some people. In most patients, this is a result of poor adherence but some patients do have extended drug resistance and minimal treatment options and achieving viral suppression is not possible.

The drugs now most commonly used in triple-class failure are the PI/rs, DRV/r and tipranavir/ritonavir (TPV/r), the integrase inhibitors RAL and elvitegravir (ELV) (not yet licensed), the CCR5 chemokine receptor antagonist MVC, the NNRTI ETV, and the fusion inhibitor enfuvirtide. The available data for DRV/r, TPV/r, RAL,ELV, ETV, and enfuvirtide show that they are most effective when used with other active drugs to which the virus is susceptible based on resistance testing and antiviral experience [45–53]. When used as the only effective agent, the likelihood of achieving virological suppression is significantly and the development of emergent resistance to the drug greater and a future opportunity for constructing an effective regimen is often lost.

A priority question the writing committee addressed was whether two or three fully active drugs should be included in the new regimen. In a meta-analysis of 10 trials of patient with triple-class virological failure and virological resistance where the study drug was added to optimised background therapy (OBT) and compared to placebo, associations were demonstrated with increased virological suppression (pooled OR 2.97) and larger CD4 count increases for the active agent [54]. OBT genotypic sensitivity scores (GSSs) were also associated with larger differences in virological suppression (P<0.001 for GSS = 0, <1 and <2) and CD4 cell count increase (GSS=0, P<0.001; GSS ≤1, P<0.002; GSS ≤2, P=0.015) between the two groups. In a further non-inferiority study, ELV was found to be non-inferior to RAL when accompanied by a boosted PI and a third agent [46].

This supports the use of at least two and possibly three of these agents in the new regimen and with this strategy, the goal of an undetectable viral load is now achievable even in most patients with multiregimen failure. A priority question addressed in this group was whether regimens with at least three fully active drugs should include NRTIs? The recommendation from the writing committee is that in constructing an optimized background, continuing/commencing NRTIs may contribute partial ARV activity to a regimen, despite drug resistance [56,57].

For those drugs with a novel mode of action (integrase and fusion inhibitors, and CCR5 antagonists), the absence of prior exposure indicates susceptibility although MVC is only active against patients harbouring CCR5 tropic virus. For DRV, TPV and ETV, the number and type of mutations inform the degree to which these drugs are active [57–59]. The potential for drug–drug interactions is also important. Etravirine can be paired with DRV/r (but not TPV/r) and MVC dosing is variable depending on the other drugs in the new regimen: however, RAL and enfuvirtide require no alteration.

Some patients can have a successfully suppressive fully active three-drug regimen constructed without a PI/r [60]. Nevertheless, where feasible a PI/r such as DRV/r should be included because of its protective effect on emergent resistance to the other drugs in the regimen although this can be given DRV/r 800mg/100mg once daily in treatment-experienced patients.
without DRV RAMs [61]. Enfuvirtide is an option in some patients despite the inconvenience of subcutaneous injection and injection site reactions. With the availability of the newer agents, dual PI/rs are not recommended [62].

The same principles regarding reviewing adherence, tolerability/toxicity issues, drug–drug/food interactions, and mental health/drug dependency problems apply. Additional adherence support is important in these patients as the reason triple-class failure has occurred often relates to past poor adherence. Additionally, the pill burden is increased and careful discussion with the patient should take place.

### 7.5 Patients with limited or no therapeutic options when a fully viral suppressive regimen cannot be constructed

#### 7.5.1 Recommendations

- We recommend accessing newer agents through research trials, expanded access and named patient programmes (GPP)
- We suggest continuing/commencing NRTIs as this may contribute partial ARV activity to a regimen, despite drug resistance (2C)
- We recommend the use of lamivudine or emtricitabine to maintain a mutation at codon position 184 of the reverse transcriptase gene (1B).
- We recommend against discontinuing or interrupting ART (1B)
- We recommend against adding a single, fully active ARV because of the risk of further resistance (1D)
- We recommend against the use of maraviroc to increase the CD4 count in the absence of CCR5 tropic virus. (1C)

#### 7.5.2 Rationale

This usually occurs following attempts in patients with triple-class failure to achieve virological suppression with the newer agents and often indicates adherence issues have not been addressed successfully or sequential addition of the newer agents has occurred without incomplete viral suppression and selection of resistance to the new drug.

There is evidence from cohort studies that continuing therapy, even in the presence of viraemia and the absence of CD4 T-cell count increases, reduces the risk of disease progression [63,64] whereas interruption may lead to a rapid fall in CD4 count and rise in viral load [65,66]. Other studies suggest continued immunologic and clinical benefits if the HIV RNA level is maintained <10,000–20,000 copies/ml [67]. Continuing or commencing NRTIs, even in the presence of known resistance may contribute partial ARV activity [55,56]. Hence, if the CD4 cell count is well maintained (>200 cells/µL), it may be better to continue the failing regimen and not change treatment until investigational agents are available that can be put together with drugs, which may have only partial activity at best, to increase the likelihood of constructing a virologically suppressive and durable regimen options.
In general, adding a single, fully active ARV to a failing regimen is not recommended because of the risk of rapid development of resistance. However, in patients with a high likelihood of clinical progression (e.g. CD4 cell count <100 cells/mm³) and limited drug options, adding a single drug may reduce the risk of immediate clinical progression, because even transient decreases in HIV RNA and/or transient increases in CD4 cell counts have been associated with clinical benefits [68]. Potential benefits must be balanced with the ongoing risk of accumulating additional resistance mutations and patients should maintain that regimen for the shortest period possible [69,70].

Where feasible, patients should be given the opportunity to enrol in research studies or expanded access programs evaluating investigational new drugs. Some drugs are likely to be available in the near future that might be sequenced in the same class (e.g. dolutegravir) although others with novel sites of action (e.g. maturation inhibitors, CD4 receptor antagonists etc) are still in earlier phases of development and some years off randomised trials. Drugs developed for and used in other settings such as pegylated Interferon that have been incidentally demonstrated to decrease viral load should not be used without discussion with an experienced HIV physician as data is either too limited or contradictory.

Several studies and an early meta-analysis suggested that CCR5 receptor antagonists were associated with significant gains in CD4 cell counts even in the presence of CXCR4 tropic virus. However, a more recent meta-analysis refuted this finding (P=0.22) when comparing with other new drugs [54].

A priority question that the writing committee addressed was whether 3TC/FTC should be used in maintaining an RT mutation at 184 in patients with limited or no therapeutic options.

Although the M184V mutation is associated with resistance to 3TC/FTC, the mutation has a broad influence on the reverse transcriptase enzyme. In vitro studies have shown that M184V-possessing enzymes have lower processivity and higher fidelity and replicate more slowly than wild-type enzymes [71]. These observations have led to the hypothesis that maintaining this mutation using 3TC/FTC would provide clinical benefit through the replication deficit provided by the M184V mutation combined with the residual antiviral activity of 3TC/FTC [72,73]. It has been shown that patients harbouring M184V due to 3TC failure who continue on 3TC monotherapy maintain lower viral loads than at baseline and rarely develop new RT or protease mutations [74]. Moreover, ceasing 3TC monotherapy has been demonstrated to result in replication capacity recovery and a reduction in CD4+/CD8+ ratio driven by the de-selection of the M184V mutation [75]. This strategy is supported by the E-184 study which was a small but randomised, open-label study of 3TC monotherapy versus no therapy in patients failing ART [76]. Monotherapy was associated with significant smaller increases in viral load, smaller declines in CD4+ cell counts, and no selection of additional reverse transcriptase mutations.

Finally, the presence of M184V mutation enhances in vitro susceptibility to TDF and this translated into a significant HIV RNA response in clinical trials of TDF intensification [77,78].

8. ART in specific populations

For some patient populations specific considerations need to be taken into account deciding when to start and the choice of ART. The following sections outline specific recommendations and the supporting rationale for defined patient populations. In parallel to guidelines on ART in adults, BHIVA also publishes guidelines on the management and treatment of specific patient populations including co-infection with tuberculosis, co-infection with viral hepatitis B or C, and HIV pregnant women. An outline of the recommendations for when to start and choice of ART, from the BHIVA guidelines for tuberculosis and viral hepatitis is summarised below. The reader should refer to the full published guidelines for these patient populations for more detailed information and guidance at the BHIVA web site (www.bhiva.org/publishedandapproved.aspx) and be aware that BHIVA clinical practice guidelines are periodically updated.

For the BHIVA adult ART 2012 guidelines new guidance on when to start and choice of ART has been developed for HIV related cancers, HIV-associated neurocognitive impairment, chronic kidney disease, cardiovascular disease and women. The guidance only considers specific issues concerning the initiation and choice of ART in these patient populations. Guidance on the management of pregnancy in HIV-positive woman has not been included.

8.1 HIV with tuberculosis co-infection

This guidance provides a brief summary of the key statements and recommendations regarding prescribing ART in HIV-positive patients co-infected with tuberculosis (TB). It is based on the BHIVA 2011 TB/HIV guidelines [1] which should be consulted for further information. The full version of the guidelines is available at:

Auditable measure
Proportion of patients with TB and CD4 count <100 cells/µL started on ART within 2 weeks of starting TB therapy

8.1.1.2 Rationale
Most patients with tuberculosis in the UK present with a low CD4 count, often <100 cells/µl. In such patients ART improves survival, but can be complicated by immune reconstitution disease (IRD) and drug toxicity. Data suggests that antiretroviral therapy can be delayed until the first two months of TB therapy has been completed but at CD4 counts <50 cells/µl the short-term risk of developing further AIDS-defining events and death is high, and ART should be started as soon as practicable and within two weeks of initiation of TB therapy [2–5]. Starting ART early in severely immunosuppressed HIV-positive patients presenting with TB is associated with decreased mortality and a lowering of the rates of disease progression but rates of IRD are high.

Patients with HIV and a CD4 cell count >350 cells/µl have a low risk of HIV disease progression or death during the subsequent six months of TB treatment, depending on age and viral load [6]. They should have their CD4 cell count monitored regularly and antiretroviral therapy can be withheld during the short-course of TB treatment.

One study performed in HIV-associated TB meningitis in the developing world, where 90% were male, the majority drug users, many with advanced disease and the diagnosis being made clinically, showed no difference in mortality starting ART early or late [7].

8.1.2 What to start

8.1.2.1 Recommendations

• We recommend efavirenz in combination with tenofovir and emtricitabine as first-line antiretroviral therapy in TB/HIV co-infection (1B)

• We recommend that when rifampicin is used with efavirenz in patients over 60kg, the efavirenz dose is increased to 800mg daily. Standard doses of efavirenz are recommended if the patient weighs less than 60kg (1C)

• We recommend that rifampicin is not used with nevirapine or ritonavir-boosted protease inhibitors (1C)

• We recommend that where effective ART necessitates the use of ritonavir-boosted protease inhibitors that rifabutin is used instead of rifampicin (1C)

Auditable measure
Proportion of patients with active TB on anti-tuberculosis therapy started on ART containing efavirenz and tenofovir and emtricitabine
8.1.2.2 Rationale

Preferred ART

HIV-related tuberculosis should be treated with a regimen including a rifamycin for the full course of tuberculosis treatment, unless there is rifamycin resistance or intolerance. Rifamycins frequently interact with antiretroviral medications and can lead to similar toxicities, notably rash and hepatitis. We recommend EFV as the preferred therapy for ART because of its confirmed potency when used in TB/HIV co-infection [8–10], and its efficacy in randomized clinical trials. We recommend that EFV be given with TDF and FTC due to the availability of a once daily co-formulation, a reduced risk of rash compared to NVP and improved efficacy at higher HIV viral loads (commonly occurring in this setting). ABC-3TC is an alternative acceptable NRTI backbone in patients with lower HIV viral loads and who are HLAB5701 negative (see Section 4.3 Which NRTI backbone).

There is significant variability in the effect that rifampicin has on EFV concentrations because of liver enzyme induction especially of CYP P450 3A4 [8,11–13]. Sub-therapeutic EFV concentrations may occur among patients who weigh more than 60 kilograms who are taking standard-dose EFV together with rifampicin, and increasing the dose of EFV from 600 mg daily to 800 mg daily may be necessary but there is a risk of increasing adverse effects. A cohort study and a small randomized controlled trial have shown that the standard adult EFV dose (600 mg daily) together with 2 nrtis is well-tolerated and was efficacious in achieving complete viral suppression among adults on concomitant rifampicin-based tuberculosis treatment although the majority of patients were of low body weight [10,14,15].

In summary, we recommend that when EFV is used with rifampicin, and in patients over 60kg, the EFV dose is increased to 800mg daily. Standard doses of EFV are recommended if the patient weighs less than 60kg. We suggest that therapeutic drug monitoring be performed at around week of starting EFV if side effects occur and the dose adjusted accordingly.

Nevirapine

Nevirapine taken with TB treatment is complicated by pharmacokinetic interactions and by overlapping toxicities especially skin rash and hepatitis. One study showed that patients co-infected with HIV and TB who initiated NVP-based ART during TB treatment had a nearly two-fold higher risk of having a detectable HIV viral load after six months compared to those taking NVP who did not have tuberculosis. However, those patients who were established on NVP at the time of initiation of TB treatment did not have a higher risk of HIV virological failure [11]. Using a higher maintenance dose of NVP (300mg bd) to overcome drug interactions has been associated with higher rates of hepatotoxicity [16]. In one randomized trial comparing NVP 200 mg twice daily at initiation to EFV 600 mg once-daily among patients with TB and HIV and CD4 counts below 250 cells/µL non inferiority of NVP was not demonstrated compared to EFV [17].

Protease inhibitors

When co-administered with rifampicin, concentrations of standard-dose protease inhibitors are decreased below therapeutic targets and cannot, therefore be recommended [18–20]. Changing the dosing of PI/rs has resulted in unacceptable rates of hepatotoxicity [21–23].

Rifabutin has little, effect on the concentrations of PI/rs but rifabutin concentrations are increased when the drug is taken together with protease inhibitors. Current recommendations
are to give rifabutin at a dose of 150 mg thrice-weekly to adults taking PI/rs. Some data suggest that 150 mg od can be given to reduce the theoretical risk of rifamycin resistance due to subtherapeutic rifabutin concentrations but this strategy may be associated with increased side effects [24–31].

Other drugs

There are few clinical data to support the use of newer nrtis, integrase inhibitors and CCR5 receptor antagonists with rifampicin or rifabutin. We recommend that physicians review the PK and other data summarised in the current BHIVA HIV and TB guidelines [1].

8.1.3 References

8.2 HIV and viral hepatitis co-infection

8.2.1 Introduction

The following guidance provides a brief summary of the key statements and recommendations regarding prescribing ART in patients with HIV/Hepatitis B and C co-infection. It is based on the BHIVA guidelines for the management of co-infection with HIV-1 and hepatitis B or C virus 2010 [1] which should be consulted for further information and to the BHIVA web site for latest updates (www.bhiva.org/publishedandapproved.aspx).

Where viral hepatitis B or C chronic infection has been diagnosed, individuals should be referred to a dedicated co-infection clinic or hepatologist for appropriate staging of their hepatitis B or C infection. The decision to initiate treatment for either HIV or viral hepatitis infections should ordinarily be made with agreement of the patient’s HIV and viral hepatitis physicians.

In patients with cirrhosis (Child-Pugh grade B/C) certain antiretroviral therapy should be used with caution and careful monitoring (including TDM) will be required by physicians experienced in the management of HIV and viral hepatitis co-infection. For further information on use of ART in patients with cirrhosis please refer to the BHIVA HIV and hepatitis B/C co-infection guidelines [1].

Summary of when to start recommendations

<table>

### 8.2.2 Hepatitis B

#### 8.2.2.1 When to start ART

**Recommendations**

- We recommend patients with HIV and hepatitis B virus co-infection who have a CD4 count between 350–500 cells/µL start ART (1C).

- We suggest patients with HIV and hepatitis B virus co-infection who have a CD4 count >500 cells/µL and who require treatment for their hepatitis B start ART (2C).

**Auditable measure**

Proportion of patients with HIV and hepatitis B virus co-infection with CD4 counts <500 cells/µL on ART

**Rationale**

Because of the negative effect of immune depletion on HBV disease progression, the availability of single drugs with high level dual hepatitis B and HIV anti-viral activity, and the increased risk of liver-related deaths in patients with CD4 counts below 500 cells/µL, co-infected patients with CD4 counts between 350 and 500 cells/µL should start ART and be treated with drugs active at suppressing both viruses [2]. Consideration can be given to some patients with CD4 counts between 350 and 500 cells/µL and HBV DNA of <2000 IU/L and no evidence of liver...
inflammation or fibrosis to close monitoring of their HIV and hepatitis B infections as an acceptable alternative strategy.

Individuals with a CD4 count >500 cells/µL who do not require hepatitis B therapy, should be monitored for HIV and hepatitis B disease progression and the need of therapy for either virus infection. Among individuals with a CD4 count >500 cells/µL who require treatment for hepatitis B infection there is the option to start ART with drugs active at suppressing both viruses. For indications to start treatment for hepatitis B infection please refer to the BHIVA guidelines on management of co-infection with HIV and hepatitis B or C virus (1).

8.2.2.2 What to start

**Recommendations**

- We recommend patients with HIV and hepatitis B virus co-infection who start ART include tenofovir and emtricitabine as part of their ART regimen, if there are no contraindications for either drug (1A)

**Auditabile measure**

Proportion of patients with HIV and hepatitis B virus co-infection starting tenofovir and emtricitabine as part of their first ART regimen

**Rationale**

Tenofovir, FTC and 3TC are agents that have antiviral activity against both HIV and hepatitis B. The efficacy of these drugs against hepatitis B has been assessed in randomized trials extending out to 5 years in mono-infected patients [3]. They are recommended agents in these guidelines for the treatment of HIV-1 infection.

All hepatitis B co-infected individuals who start ART, should commence a regimen containing TDF and FTC. Hepatitis B treatment options for patients declining ART are discussed elsewhere [1].

If an individual becomes intolerant or is unable to commence a TDF containing regimen, TDF should be substituted with either adefovir or entecavir and an alternate antiretroviral agent added to the regimen. No individual co-infected with hepatitis B should receive a regimen containing 3TC or FTC monotherapy as its use may result in the selection of the YMDD mutation [4,5]. HBV resistance to TDF is rare and combination with 3TC and FTC has been demonstrated to be effective at suppressing HBV DNA and may induce hbeag seroconversion and may reduce the risk of HBV breakthrough [6].

In individuals virologically failing hepatitis B therapy a resistance test should be taken and new therapy for HIV and hepatitis B commenced only after close consultation with a specialist virologist or specialists in HIV/viral hepatitis co-infection clinic. Co-infected individuals who need to start a new ART regimen for reasons such as ART virological failure should ensure that effective anti hepatitis B therapy is continued in addition to their new ART regimen. Abrupt withdrawal of effective treatment may lead to a flare in hepatitis B replication with liver damage. This may be particularly severe in patients with cirrhosis.
8.2.3 Hepatitis C

8.2.3.1 When to start ART

Recommendations

- We recommend patients with HIV and hepatitis C virus co-infection be assessed for HCV treatment (GPP)
- We recommend patients with HIV and hepatitis C virus co-infection and CD4 count between 350-500 cells/µL start ART: (i) immediately if HCV treatment is deferred, (ii) after initiation of HCV treatment if this is starting immediately.1 (1C)
- We recommend patients with HIV and hepatitis C virus co-infection and CD4 count <350 cells/µL start ART before HCV treatment (1B)

Auditble measure
Proportion of patients with HIV and Hepatitis C virus co-infection and CD4 counts <500 cells/µL on ART

Rationale
HCV is believed to have a deleterious effect on HIV disease progression [7,8]. In addition, HIV has an impact on hepatitis C infection. The rate of liver fibrosis progression is faster in HIV/HCV co-infected patients particularly among patients with low CD4 cell counts [9,10,11]. The estimated risk of cirrhosis was two-fold higher in individuals with HIV/HCV co-infection compared with those with HCV mono-infection [12]. Liver mortality rates are reportedly higher in those with a low CD4 count [13] and hepatocellular carcinoma (HCC) is believed to occur at a younger age and within a shorter time period [14]. All patients with chronic hepatitis C should be assessed for their HCV related liver disease as well as for their stage of HIV infection.

Cohort studies examining the effect of ART on the natural history of HCV infection have shown inconsistent results [15,16]. A few studies have concluded that HIV viral load, but not CD4, was directly related to fibrosis progression rate [17], a finding consistent with the role of HIV viral load both as a predictor of AIDS survival and as a predictor of survival in HCV/HIV co-infected individuals [18,19] and also in HCV/ HIV co-infected liver transplant recipients [20]. ART is not associated with serious histological liver disease [21].

For these reasons, patients with HIV and hepatitis C infection with CD4 counts <500 cells/µL should start ART. This should be immediate if: (i) CD4 count is <350 cells/µL, irrespective of whether HCV treatment is planned or not, (ii) CD4 count is between 350 and 500 cells/µL and treatment for HCV has been deferred. For patients with CD4 counts between 350 and 500 cells/µL starting HCV treatment immediately, initiation of ART should be delayed until after start of HCV treatment. Individual factors will determine the timing of ART after HCV treatment is commenced.
Individuals with a CD4 count greater than 500 cells/µL who defer hepatitis C therapy, should be monitored closely for HIV or hepatitis C disease progression and the need for therapy for either virus.

8.2.3.1 What to start

Recommendations

- We recommend that potential pharmacokinetic interactions between antiretrovirals and anti-hepatitis agents are checked prior to administration (with tools such as: http://www.hep-druginteractions.org) (GPP)

Auditable measure

Record in patient’s notes of potential pharmacokinetic interactions between antiretrovirals and ant-viral hepatitis C agents

Rationale

Significant pharmacokinetic and pharmacodynamic interactions have been reported between antiretroviral drugs and the newer anti hepatitis agents. Boceprevir and telaprevir undergo extensive hepatic metabolism, boceprevir primarily by way of the aldoketoreductase system but also by the cytochrome P450 enzyme system; whereas telaprevir is metabolized only by the cytochrome P450 enzyme system, and the main route of elimination is via the faeces with minimal urinary excretion. Both boceprevir and telaprevir are potent cytochrome P450 inhibitors. Therefore drug–drug interactions (DDI) are likely when used together with antiretroviral drugs. Currently, studies have been completed for TDF, EFV, ATV/r and RAL with telaprevir and for TDF, DRV/r, LPV/r, ATV/r, EFV and RAL for boceprevir [22–27] Other DDI studies are planned and currently information is available at www.hep-druginteractions.org.

Due to the rapidly emerging data on the use of these newer agents and the complexities of the drug interactions, we suggest that the treatment of HCV infection in HCV/HIV co-infected patients should be carried out as part of a clinical trial. If a suitable clinical trial is not available, such treatment should only be carried out by physicians who have experience with the new HCV protease inhibitors and/or directly acting agents. Extreme care should be given to drug–drug interactions in patients who are taking HIV treatment. HIV treatment should be switched to agents where DDI have been studied.

8.3 HIV-related cancers

Summary auditable measures

Proportion of patients with an AIDS defining malignancy on ART

Proportion of patients with a non-AIDS defining malignancy on ART

Record in patient’s notes of potential pharmacokinetic drug interactions between antiretrovirals and systemic anti-cancer therapy

8.3.1 When to start ART: AIDS-defining malignancies

Kaposi sarcoma, high-grade B-cell non-Hodgkin lymphoma and invasive cervical cancer are all AIDS defining illnesses and are thus indications to commence ART regardless of CD4 cell count of HIV viral load.

8.3.1.1 Kaposi sarcoma (KS)

Recommendation

- We recommend starting ART in HIV positive patients with Kaposi sarcoma (1A)
Rationale
ART has been shown to reduce the incidence of KS in HIV cohort studies [1–4], to prevent KS in patients on ART [5], and in addition increases the time to disease progression in KS [6], improves prognosis in KS and prolongs survival in KS [7-9]. When initiating ART for KS, there appears to be no difference in response or outcome of KS between different HIV treatment regimens [5,10]. Therefore, no recommendation can be made on choice of HIV therapy for patients with KS.

8.3.1.2 Non-Hodgkin lymphoma (NHL)

Recommendation
• We recommend starting ART in HIV positive patients with non-Hodgkin lymphoma (1B)

Rationale
ART has been shown to reduce the incidence of NHL [2,11–20] and to improve the outcome [9,21–24]. Before ART was available, the treatment of NHL with standard doses of chemotherapy produced marked toxicity and a high incidence of opportunistic infections [25]. In an attempt to decrease toxicity, modified dose chemotherapy regimens were used by the AIDS clinical trials group (ACTG). However, the reduced opportunistic infections were offset by the lower response rates [26]. Since the widespread availability of ART, two retrospective studies reported higher tumour response rates and overall survival in HIV seropositive patients with systemic NHL who were treated with CHOP chemotherapy and concomitant ART compared to those who were treated with CHOP alone [21,22]. Similarly, in a separate study of liposomal doxorubicin in combination with cyclophosphamide, vincristine and prednisolone in HIV-associated NHL, improvement in survival was associated with HIV viral control, although complete remission rates were independent of HIV viral load [27].

Further evidence to support the use of ART with chemotherapy in both KS and NHL is the finding from historical comparisons that the fall in CD4 count during chemotherapy is less profound when ART is prescribed concomitantly and that the duration of lymphocyte subset suppression is briefer [28–31].

However, a number of US intergroup studies have either withheld ART during chemotherapy [32,33] or delayed the initiation of ART [34]. The rationale for this approach includes avoiding adverse pharmacokinetic and pharmacodynamic interactions between ART and chemotherapy and the theoretical concern that protease inhibitors may inhibit lymphocyte apoptosis and thus contribute to chemoresistance of lymphomas [35]. Although no new HIV mutations were identified, these studies were small and ART was promptly reinstituted after abbreviated chemotherapy. Nevertheless it took 12-18 months after completing the chemotherapy for plasma HIV viraemia to become undetectable in many patients [33]. Importantly, patients with NHL frequently present with CD4 counts <200 cells/µL and thus the reduction in CD4 count associated with systemic chemotherapy and structured suspension of ART is not ideal.
8.3.1.3 Cervical cancer

Recommendation

- We suggest starting ART in HIV positive patients with cervical cancer (2C)
- We recommend starting ART in HIV positive patients who are commencing radiotherapy or chemotherapy for cervical cancer (1D)

Rationale

There is less clear evidence to support starting ART in women diagnosed with invasive cervical cancer, despite its status as an AIDS defining illness. Co-registration studies have shown that ART has not reduced the incidence of cervical cancer [36–38], moreover the effects of ART on pre-invasive cervical dysplasia have been variable with some studies suggesting that ART causes regression of cervical intraepithelial neoplasia [39–45] and others showing no beneficial effect of ART [46–49]. The effects of ART on outcomes in HIV positive women with invasive cervical cancer have not been reported but analogies with anal cancer may be drawn as the malignancies share common pathogenesis and treatment modalities. Combined chemoradiotherapy in anal cancer has been shown to cause significant and prolonged CD4 suppression even when ART is administered concomitantly [50–53]. Similarly the toxicity of chemoradiotherapy for HIV-associated anal cancer appears to be less profound amongst patients given ART compared to historical controls [51,52,54–59].

8.3.2 When to start ART: non-AIDS-defining malignancies

Recommendation

- We suggest starting ART in HIV positive patients with non-AIDS defining malignancies (2C)
- We recommend starting ART in HIV positive patients who are commencing immunosuppressiveradiotherapy or chemotherapy for non-AIDS defining malignancies (1C)

Rationale

Whilst ART has little effect on the incidence of non-AIDS defining malignancies (NADMs) [2,60–67] and there is no evidence that ART alone causes regression of NADMs, the immunosuppressive effects of both chemotherapy [28–31] and radiotherapy [50–53] may justify starting ART in HIV positive individuals who are commencing systemic anticancer therapy or radiotherapy.

8.3.3 What to start

Recommendation

- We recommend that potential pharmacokinetic interactions between antiretrovirals and systemic anticancer therapy are checked prior to administration (with tools such as: http://www.hiv-druginteractions.org ) (GPP)
Rationale

Significant pharmacokinetic and pharmacodynamic interactions have been reported between antiretroviral drugs and systemic anticancer therapies. The mechanisms of the pharmacokinetic interactions include the inhibition and induction by antiretroviral agents of enzymes, especially the cytochrome P450 family and UGT (uridine diphospho-glucuronosyl transferase) isoenzymes, involved in the catabolism and activation of cytotoxic chemotherapy agents. In addition, competition for renal clearance, intracellular phosphorylation and ABC (ATP binding cassette) transporters, has been hypothesised to contribute to these drug interactions [68]. Similarly, pharmacodynamic interactions, in particular overlapping toxicities between antiretrovirals and systemic anticancer therapy suggest that some drug combinations should be avoided in patients with HIV-associated cancers. Much of the guidance on the use of individual antiretroviral agents with systemic anticancer therapy comes from reviews of potential drug interactions rather than from clinical studies [68–70]. The pharmacokinetic interactions between antiretrovirals and systemic anticancer therapy are not confined to cytotoxic chemotherapy agents and extensive interactions with newer targeted therapies such as imatinib, erlotinib, sorafenib, bortezomib and temsirolimus have been described [70].

Recommendation

- We suggest avoiding ritonavir-boosted ART in HIV positive patients who are to receive cytotoxic chemotherapy agents that are metabolised by the CYP450 enzyme system (2C)

Rationale

In general, clinically important pharmacokinetic drug interactions with systemic anticancer therapies are most common with PI/r based ART and most clinicians avoid these combinations where possible. For example, in a cohort study, the rates of severe infections and severe neutropenia following chemotherapy for AIDS related NHL were significantly higher amongst patients receiving concomitant PI (mainly ritonavir boosted) than in those on NNRTI-based ART regimens, although there was no difference in survival between the groups [71]. Furthermore, case reports of clinically significant life-threatening interactions between ritonavir-boosted based ART and docetaxel [72], irinotecan [73], vinblastine [74] have been published.

Recommendation

- We recommend against the use of atazanavir in HIV positive patients who are to receive irinotecan (1C)

Rationale

The camptothecin cytotoxic agent irinotecan is extensively metabolised by UGT1A1 isoenzymes that are inhibited by atazanavir [75]. In patients with Gilbert’s syndrome, who have a congenital deficiency of UGT1A1, irinotecan administration has led to life-threatening toxicity [76].
**Recommendation**

- We suggest avoiding antiretroviral agents in HIV positive patients who are to receive cytotoxic chemotherapy agents that have overlapping toxicities (2C)

**Rationale**

Both antiretroviral agents and systemic anticancer therapies have substantial toxicity and where these overlap it is likely that the risk of toxicity is greater. For example, zidovudine commonly causes myelosuppression and anaemia [77] which are also frequent side effects of cytotoxic chemotherapy and so these should not be co-prescribed where possible. Similarly, dideoxynucleosides cause peripheral neuropathy [78], a common toxicity of taxanes and vinca alkaloids, so co-prescribing should be avoided. Both zidovudine and dideoxynucleosides are no longer recommended for initiation of ART but some treatment-experienced patients may still be receiving these drugs and alternatives should be considered.

8.4 HIV-associated neurocognitive impairment

8.4.1 Introduction

With the widespread use of effective combination antiretroviral therapy, the incidence of severe HIV-associated cerebral disease has declined dramatically [1], however more subtle forms of brain disease, known as HIV-associated neurocognitive (NC) disorders are reported to remain prevalent [2]. This NC deficit may present with a wide spectrum of clinical symptoms, however typically includes patterns involving ineffective learning and problems with executive function, rather than pure difficulties in formulating new memory (the cortical defect typical of Alzheimer's Disease [3]).
Given the changing picture of this disease, a revised nomenclature system has proposed classifying subjects with abnormal neuropsychological testing results into three categories based on patient’s symptoms, measured via the activities of daily living (ADL) scale [2]. Subjects with abnormal neuropsychiatric testing results, who are otherwise asymptomatic are classified as having HIV-associated asymptomatic neurocognitive impairment (ANI), those who are mildly symptomatic are classified as having HIV-associated mild neurocognitive disorder (MND) and those who are severely symptomatic are classified as having HIV-associated dementia (HAD). The clinical relevance of ANI, namely asymptomatic subjects with abnormal results on neuropsychological testing, remains unclear.

Reports describing rates of NC impairment vary with some groups describing that up to 50% of HIV positive subjects meet the above diagnostic criteria [4]. However such reports should be interpreted with caution as asymptomatic subjects are often included and not all reports correct for effective antiretroviral use. A Swiss cohort has reported 19% of aviraemic HIV positive subjects to meet the classification for MND or above [5].

Risk factors for the development of NC disorders are poorly understood and are likely to be multifactorial including both HIV disease factors [6] and concomitant diseases [7]. Although it is possible the choice of combination antiretroviral therapy a subject receives may influence NC function, this is a controversial area without definitive evidence. The following recommendations apply to patients with symptomatic HIV-associated neurocognitive disorders.

**8.4.2 When to start ART**

**8.4.2.1 Recommendation**

- We recommend patients with symptomatic HIV-associated neurocognitive disorders start ART irrespective of CD4+ lymphocyte count (1C)

**Auditable measure**

Proportion of patients with symptomatic HIV associated neurocognitive disorders on ART

**8.4.2.2 Rationale**

Current evidence suggests NC function improves after commencing antiretroviral therapy for the first time [8] in both cognitively-symptomatic [9] and –asymptomatic [10] subjects. However these studies have been undertaken in individuals with other indications to commence antiretroviral therapy, in general with CD4+ lymphocyte counts in the designated range where treatment is recommended. For subjects with higher CD4+ lymphocyte counts, the ongoing START study will prospectively assess NC function in HIV positive subjects commencing antiretroviral therapy at an earlier stage of HIV disease.

Therefore, antiretroviral therapy is recommended in NC symptomatic subjects whose CD4+ lymphocyte count itself is an indication to commence therapy.

In the absence of scientific data, in cognitively-symptomatic subjects with higher CD4+ lymphocyte counts in whom antiretroviral therapy would not be otherwise indicated, a recommendation to consider commencing antiretroviral therapy is based firstly on the observed
improvements in cognitive function reported in subjects with lower CD4+ lymphocyte counts commencing therapy [8], and secondly in order to avoid a future decline in CD4+ lymphocyte count in such subjects, given the well described association between low nadir CD4+ lymphocyte count and NC impairment [6].

Sub-optimal adherence to therapy may occur more frequently in subjects with NC impairment, hence adequate support services to optimise adherence are essential.

8.4.3 What to start

8.4.3.1 Recommendation

• We recommend patients with HIV-associated NC disorders start standard combination ART regimens. (1C)

Auditable measure

Proportion of patients with HIV associated NC disorders on ART containing two NRTIs and either a NNRTI or a PI/r or a INI

8.4.3.2 Rationale

Although during the earlier years of antiretroviral therapy, clear benefits on cerebral function of individual antiretroviral drugs such as zidovudine were reported [11] and the benefits of combination therapy overall are well described [8], data are sparse regarding any differences in these benefits between individual agents or combinations. Within cohort studies, the use of the NRTI class within antiretroviral regimens has been associated with a reduced risk of severe HIV-associated dementia [12] compared to the use of other regimens, however the confounders of a cohort study limit the interpretation of these data.

Recent, attempts have been made to establish a relationship between cognitive function and CNS antiretroviral drug delivery based on an antiretroviral scoring system known as the Clinical Penetration Effectiveness (CPE) Score [13]. The CPE score aims to rationally score the cerebral effects of individual antiretroviral agents. However the system is predominantly designed around pharmacokinetic modelling rather than pharmacodynamic endpoints such as data describing changes in NC function. Studies which have assessed the correlation between the CPE scores of antiretroviral regimens with NC function report conflicting findings with some cohorts reporting a positive association [14-15], and others cohorts describing a negative association [16]. Given the potential flaws outlined in the design of the CPE score, a lack of prospective clinical data and discrepancies in findings within cohort studies, the CPE score should not influence therapeutic decisions in subjects with NC impairment commencing antiretroviral therapy.

One small prospective study has assessed the cerebral effects of three different antiretroviral regimens in neurologically asymptomatic subjects reporting greater improvement in NC function in subjects commencing a quadruple nucleoside regimen compared to an EFV or ATV/r containing regimen [17]. However subjects were asymptomatic from a neurological point limiting the relevance of these findings to neurologically symptomatic subjects.
The improvements in NC function observed with zidovudine monotherapy [11] and the greater improvements in NC function observed with a zidovudine containing quadruple nucleoside regimen compared to other ART regimens [17], raise the possibility of selecting a zidovudine containing antiretroviral regimen in subjects with NC impairment. On the converse a lack of comparator data for zidovudine monotherapy and potential toxicities arising from zidovudine use may limit the relevance of these data. Of note, further to peripheral toxicities which are well described with zidovudine use, biomarker data suggest there may also be central nervous system toxicities associated with the use of zidovudine containing regimens [18].

In summary we recommend patients with NC impairment start standard combination ART regimens and the choice should be determined, as with other patients, by different factors including base line viral load, side effects profile, tolerability, drug–drug interactions and patient preference.

8.4.3.3 Novel antiretroviral strategies and NC function

Novel antiretroviral strategies, including protease-inhibitor monotherapy continue to be assessed in clinical trials as cost-beneficial treatment regimens with the potential for reduced long-term toxicities. Concerns have been raised regarding the cerebral effects of PI monotherapy [19], with such concerns based on the hypotheses that PI monotherapy comprises of only one effective antiretroviral agent which may not adequately suppress ongoing HIV replication in sanctuary sites such as the CNS, and on pharmacokinetic modelling which suggests that not all protease-inhibitors have optimal penetration across the blood-brain-barrier [13]. Furthermore, isolated cases describing the evolution of CNS disease in previously stable HIV positive subjects receiving PI monotherapy have been reported [20].

One study was specifically designed to assess the cerebral effects of LPV/r mono-therapy [21], however this study was terminated early due to a lack of efficacy in the plasma compartment. Although cases of CNS disease were reported within this study, such results must be interpreted with caution as virological endpoints in the plasma compartment were not met and therefore such cases may be driven by poor antiretroviral efficacy per se, rather than distinct CNS disease itself [22].

In the MONET study assessing DRV/r versus standard therapy, no differences in patient reported cognitive function are observed between the study treatment arms over three years of therapy [23]. Although reassuring, these data represent changes in patient reported observations rather than observations from formal neuropsychological testing. Interestingly, in a small sub-study within MONET, improvements in detailed neuropsychological testing and improvements in cerebral bio-markers measured via imaging techniques, were reported in both treatment arms [24].

In the ongoing UK PIVOT study, detailed neuropsychological testing is being assessed prospectively in subjects on PI monotherapy versus standard therapy, the results of which will be of great interest to this field.

Given the above theoretical concerns regarding the CNS activity of PI monotherapy, and for the majority of HIV positive subjects it may be possible to select other antiretroviral regimens, we suggest this approach is currently avoided in neurologically symptomatic subjects.
**8.4.4 Modification of antiretroviral therapy**

**8.4.4.1 Recommendation**

In patients with ongoing or worsening NC impairment despite ART we recommend the following best practice management:

- Best practice management should include (GPP):
- Re-assessment for confounding conditions
- Assessment of CSF HIV RNA, CSF HIV genotropism and genotyping of CSF HIV RNA
- In subjects with detectable CSF HIV RNA, modifications to antiretroviral therapy should be based on plasma and CSF genotypic and genotropism results

**8.4.4.2 Rationale**

Several published randomised controlled studies, assessing both intensification of antiretroviral therapy with a new antiretroviral agent [25] and with adjunctive therapies [26-29] have been published. Unfortunately, none of these studies describe improvements in cognition subsequent to the study interventions. Without evidence based interventions, below outlines a best practice approach based on the current literature.

As HIV-associated NC disorders are a diagnosis of exclusion, re-evaluation of subjects with ongoing NC impairment despite antiretroviral therapy for confounding conditions with expert input from both other clinical specialties such as psychiatry, neurology, and neuropsychology is recommended and where possible input from an HIV-neurology service.

Assessment of CSF HIV RNA, CSF HIV genotropism and genotypic analysis of CSF RNA may be useful tools in the management of subjects with ongoing NC for the following reasons; firstly data from cohorts of untreated HIV positive subjects would suggest CSF HIV RNA to be greater in subjects with HIV-associated dementia and cognitive decline [30,31] and therefore suppression of CSF HIV RNA may be beneficial for cognitive function. Secondly, in subjects with ongoing NC impairment, higher degrees of genetic diversity between HIV viral strains in the CSF and plasma compartment may exist [32], even in subjects with undetectable plasma HIV RNA [33]. Therefore, assessment for CSF HIV resistance may be worthwhile in order to tailor antiretroviral therapy.

8.5 Chronic kidney disease

8.5.1 When to start ART

8.5.1.1 Recommendation

• We recommend patients with HIV-associated nephropathy (HIVAN) start ART immediately irrespective of CD4 cell count (1C)

• We recommend patients with end-stage kidney disease who are suitable candidates for renal transplantation start ART irrespective of CD4 cell count (1C)

Auditable measure

Proportion of patients with HIV associated nephropathy (HIVAN) started on ART within 2 weeks of diagnosis of CKD

8.5.1.2 Rationale

The use of ART has been associated with a decline in the incidence of HIVAN in HIV cohort studies [1], with renal histological improvement in case reports [2–3], and with delayed progression to end-stage kidney disease in case series [4–5]. In the UK, most HIVAN cases are encountered in patients with advanced immunodeficiency who were not previously known to be HIV positive or who disengaged from care or who declined ART [6]. HIVAN is rare in patients with CD4 cell counts >350 cells/µL or with undetectable HIV RNA levels [7]. Patients presenting with higher levels of proteinuria (urine ACR >70mg/mmol or urine PCR >100mg/mmol or urine protein excretion >1g/24h) or proteinuria with haematuria (urine ACR >30mg/mmol or urine PCR >50mg/mmol) or stage 4/5 CKD should be referred for specialist assessment and a renal biopsy considered; those found to have HIVAN should start ART immediately irrespective of CD4 cell count.
For chronic kidney disease (CKD) other than HIVAN, there is limited information on the natural history per se and on whether ART confers renal benefit. Immunodeficiency is a potent risk factor for CKD [8-9]. The majority of patients with CKD have (nadir) CD4 cell counts <350 cells/µL and thus qualify for ART as per current treatment guidelines. There are no data to provide guidance on whether HIV-positive patients with (or at risk of developing) CKD benefit from earlier ART initiation. Nonetheless, HIV replication, immune activation and inflammation may play a role in the pathogenesis of kidney diseases or contribute to kidney disease progression in some patients [10]. For this reason ART should be considered in those presenting with chronic kidney disease other than HIVAN.

Renal transplantation is the treatment of choice for those requiring renal replacement therapy. Patients to be considered for renal transplantation are required to have suppressed HIV RNA levels and to have CD4 cell counts >200 cells/µL [11], and should start ART, irrespective of CD4 cell count.

8.5.2 What to start

8.5.2.1 Recommendations

- We recommend against the use of antiretroviral drugs that are potentially nephrotoxic, in patients with stages 3–5 CKD if acceptable alternative antiretroviral agents are available. (GPP)

- We recommend dose adjustment of renally cleared antiretroviral drugs in patients with reduced renal function (GPP)

Auditable measure

Number of patients with CKD stages 3-5 on ARVS that are potentially nephrotoxic and record of rationale

Record in patient’s notes of calculated dose of renally cleared ARVs in patients with CKD stage 3 or greater.

8.5.2.2 Rationale

There are no data from randomised controlled clinical trials to inform antiretroviral treatment decisions in patients with CKD. The risk of CKD is increased with older age, reduced eGFR, hypertension, diabetes and with cumulative exposure to indinavir, TDF, atazanavir and, to a lesser extent, lopinavir [12,13]. Indinavir use is no longer recommended in view of the high incidence of renal complications: crystalluria and pyuria are reported in 20-67% [14–16] and nephrolithiasis, tubulo-interstitial nephritis and gradual loss of renal function in 4-33% of patients [14,17–20].

Tenofovir (TDF) has been associated with falls in eGFR [12, 21-22], accelerated decline in eGFR [9], acute renal failure [23], tubulo-interstitial nephritis [24], chronic kidney disease [9, 12], renal tubular dysfunction [13, 25] and Fanconi syndrome [26-27]. The incidence of TDF associated renal toxicity is low in clinical trials and cohort studies of the general HIV population [28-29]. Older age, pre-existing renal impairment, co-administration of didanosine or (ritonavir-boosted)
protease inhibitors, advanced HIV infection and low body mass appear to increase the risk of renal complications [9, 13, 25, 27, 30-31].

Atazanavir (ATV) has been associated with reductions in eGFR [32], nephrolithiasis and tubulo-interstitial nephritis [13, 24, 33], and chronic kidney disease [12]. The incidence of renal stones with ATV in one cohort was 7.3 per 1000 person-years, with almost half of those who developed renal stones having eGFR <60 at the time of ATV initiation [34].

The nephrotoxic potential of both TDF and ATV is low in patients with normal renal function. However in patients with chronic kidney disease and impaired renal function (eGFR < 75 ml/min/1.73m²), alternative ARVs should be considered.

In patients undergoing renal transplantation, protease inhibitors give rise to challenging drug-drug interactions with calcineurin-inhibitors (http://www.hiv-druginteractions.org). Post-transplantation, acute allograft rejection and impaired renal function are common [35]. We suggest TDF and ATV are avoided in patients who are awaiting or who have undergone renal transplantation, and that specialist advice is sought regarding choice and appropriate dose of ARVs.

Non-nucleoside reverse transcriptase inhibitors, integrase inhibitors, ABC and 3TC have not been associated with CKD and can be used in HIV positive patients with CKD. In patients with impaired renal function, specific ARV drugs (all NRTIs except ABC) may need to be dose-adjusted [36]. Impaired survival has been reported with ART prescription errors in patients undergoing dialysis [37]. We recommend dose adjustment of renally cleared ARVs in patients with renal failure but caution against the risk of over-interpreting estimates of renal function for this purpose as true measures of renal function may be substantially higher in patients with mild-moderate renal impairment. Specific ARVs which require dose adjustment in patients with reduced renal function include: 3TC, FTC, TDF, DDI, ZDV and MVC (depending on PI use). For further information and advice the reader should refer to the SPCs for each ARV.

8.5.3 References

8.6 Cardiovascular disease

8.6.1 Introduction
Cardiovascular disease (CVD) is a leading cause of non-AIDS morbidity and mortality among HIV positive individuals [1,2] and an increased risk of CVD events has been observed when compared with HIV negative populations [3-8]. This has been attributed to the increased prevalence of surrogate markers of CVD (such as dyslipidaemia) and the pro-inflammatory state associated with HIV infection. However, because ART may not mitigate (or indeed may exacerbate) these effects, caution is required in extrapolating from these markers to effects on overall mortality. The following recommendations apply to patients with or at high risk of CVD.

8.6.2 Definition and assessment of CVD risk
For the purposes of these guidelines, patients with an elevated CVD risk are as defined in the JBS2 guidelines [9] and include:

- People with any form of established atherosclerotic CVD
- Asymptomatic people who have an estimated multifactorial CVD risk >20% over 10 years
- People with diabetes mellitus (type 1 or 2)
- People with elevated blood pressure >160 mm Hg systolic or >100 mm Hg diastolic, or lesser degrees of blood pressure elevation with target organ damage
- People with elevated total cholesterol to high density lipoprotein (HDL) cholesterol ratio >6.0
- People with familial dyslipidaemia

NICE does not recommend a specific CVD risk calculation for the UK population [10]. Cohort data have demonstrated that the observed myocardial infarction (MI) rates in HIV seropositive people in developed countries paralleled those predicted by the Framingham risk equation [11] but the extent to which this can be extrapolated to women and men of non-European ethnicity is unknown. Therefore there is insufficient evidence to recommend a specific CVD risk calculation for the population of HIV positive adults in UK.

The Framingham CVD risk calculator works reasonably well in HIV-positive populations, although it is worth noting that it was not developed for use in non-White groups. Other algorithms may be better suited to these populations. A CVD risk calculator has been developed for use in HIV-positive populations (www.chip.dk/TOOLS) [29], although it should be noted that this provides 5-year risk estimates rather than the usual 10-year estimates. Alternatively, the QRISK calculator (www.qrisk.org) or the QIntervention tool (http://qintervention.org), which also provide an estimate of the risk of developing type II diabetes, can be used.

8.6.3 When to start ART
There are insufficient data to inform whether CVD risk should affect the decision to start ART
The SMART trial provides the only randomised data about the effect of ART on CVD risk, but was not powered for a CVD endpoint. Fewer major CVD events were observed in the viral suppression arm but the difference was not statistically significant [12]. In a post hoc analysis, HIV viral load <400 copies/ml was associated with fewer CVD events suggesting that suppression of viraemia may have been protective; CD4 count was not significantly associated with CVD events [13,14].

Several cohort studies have examined changes in rate of cardiovascular events in HIV-positive populations over time since the introduction of ART but no clear protective effect was found [15-18]. In the HOPS cohort baseline CD4 count <350 cells/µL was associated with increased CVD risk, but 350-500 cells/µL and use of ART were not; in a parallel case control study, cases were more likely to have a current (but not baseline or nadir) CD4 count of 350-500 cells/µL [19]. The Data Collection on Adverse events of Anti-HIV Drugs (D:A:D) study found that untreated patients had a lower incidence of MI than those on ART [20] and risk increased with longer exposure to combination therapy [21].

While there is uncertainty as to whether treating HIV infection reduces CVD risk, there is good evidence from RCTs that interventions targeted at modifiable CVD risk factors are of benefit. For this reason all HIV positive adults should be assessed for CVD risk annually and interventions targeted at improving modifiable risk factors.

**8.6.4 What to start**

**8.6.4.1 Recommendations**

- We suggest avoiding abacavir (2C), fosamprenavir/ritonavir (2C) and lopinavir/ritonavir (2C) in patients with a high CVD risk, if acceptable alternative antiretroviral drugs are available.

**Auditable measure**

Number of patients with high CVD risk on either abacavir or fosamprenavir/ritonavir or lopinavir/ritonavir and record of rationale

**8.6.4.2 Rationale**

Modifiable risk factors should be addressed in all patients with high CVD risk.

No RCTs has been powered to assess the CVD risk associated with the use of individual ARVs and a history of CVD may be an exclusion criteria. A meta-analysis of all RCTs where ABC was assigned randomly found no association with MI, but the event rate in the population was low; the extent to which these findings can be extrapolated to a population with high CVD risk is unknown [22]. Although a post-hoc analysis of the SMART study did find such an association, use of ABC was not randomised [23].

Two cohorts have found a strong association between recent ABC use and MI [24,25] while another, did not [26,27]; all were limited in their ability to adjust for presence of CVD risk factors. An analysis of the manufacturer’s trial registry found no association [28], but the trials only enrolled patients with low CVD risk. One case-control study (which did not adjust for
important CVD risk factors) did find an elevated risk of MI associated with ABC use [7] but another did not [29]. Cerebrovascular events were more common in patients exposed to ABC in two cohort studies [8,27] while another found a protective effect [26]. In view of the uncertainty about the safety of ABC in patients with a high CVD risk, we suggest the use of alternative agents where possible.

Early studies of PI exposure and risk of MI gave conflicting results, some reporting an increased risk [5,30] while others did not [3,15,31]. The D:A:D cohort, with longer follow-up, reported an increasing risk of MI with years of PI exposure (independent of measured metabolic effects) [21]. Cumulative exposure to indinavir and LPV/r were associated with increasing risk of MI (adjusted relative risk per year for LPV/r 1.13 (95% CI 1.05–1.21); relative risk at 5 years 1.84) [25]. Case-control studies reported similar associations for LPV/r [7,29] and FPV/r [29] but in one of these important CVD risk factors were not included [7]. A further study found no association between PI exposure and all cerebrovascular events [8]. An updated analysis has recently reported no association between ATV/r use and an increased risk of MI (add CROI 2012 ref).

Although there has been insufficient data to include DRV/r in these analyses, in patients with a high CVD risk, we suggest the use of alternatives to LPV/r and FPV/r where possible.

In the MOTIVATE studies for treatment-experienced patients, coronary artery disease events were only reported in the MVC arm (11 in 609 patient years), while there were none in the placebo arm (0 in 111 patient years); those affected generally had pre-existing CVD risk. No such signal was found in the MERIT study for treatment-naive patients. Maraviroc has also been associated with postural hypotension when used at higher than recommended doses in healthy volunteers; patients with a history of postural hypotension, renal impairment or taking antihypertensive agents may be at increased risk [32]. In view of the limited data available, special caution should be exercised in the use of MVC in patients with a high CVD risk and use of alternative agents where possible considered.

8.7 Women

8.7.1 Introduction

The following guidance considers issues concerning the initiation and choice of ART for HIV positive women who are not currently pregnant. For guidance on the management of pregnancy in HIV-positive woman please refer to the BHIVA pregnancy guidelines [1].

There are few specific data on ART treatment in women other than in pregnancy. Data available are largely from a meta-analysis, post hoc analyses or derived from cohort studies. The majority of the randomised clinical trial data on ART comes from studies that have enrolled mostly male subjects. If RCTs do enrol women the numbers are often too small to draw significant gender based conclusions.

Approximately one third of people diagnosed with and accessing care for HIV in the UK are women [2]. A majority are of child bearing age but the age range is increasing, adding the complexity of menopause and its sequelae to the management of HIV positive women. Many HIV positive women in the UK are of African heritage and face overlapping challenges to their health and wellbeing [3].

Women’s experience of HIV reflects multiple social and cultural influences, which when combined with sex specific biological factors influences individual responses to HIV.

8.7.2 When to start

8.7.2.1 Recommendations

- We recommend therapy naïve HIV positive women who are not pregnant start ART according to the same indicators as in men (see Section 4: When to start) (1A)

Auditable measure

Proportion of HIV positive women with CD4 cell count <350 cells/µL not on ART

8.7.2.2 Rationale

Gender differences in HIV viral load and CD4 count at different stages of infection have been observed [4] but have not been consistently associated with long term clinical outcomes for HIV positive women. Based on current data the indications for starting ART do not differ between women who are not pregnant and men.

Gender-specific socio economic and cultural factors may impact on women’s ability to access care and manage their medication, compromising their ability to initiate and adhere to therapy, and require support from the multidisciplinary team.
8.7.3 What to start

8.7.3.1 Recommendations

- We recommend therapy naïve HIV positive women start ART containing two NRTIs and either a ritonavir-boosted protease inhibitor, or a NNRTI or an integrase inhibitor (1A), as per therapy naïve HIV positive men.

- We recommend therapy naïve HIV positive women start ART with preferred or alternative NRTI backbone and third agent as per therapy naïve HIV positive men (See Section 5.1: What to start: summary recommendations) (1A). Factors such as potential side effects, co-morbidities, drug interactions, patient preference and dosing convenience need to be considered in selecting ART in individual women.

- We recommend both HIV positive women of child bearing potential and health care professionals who prescribe ART are conversant with the benefits and risks of ARV agents for both the health of the HIV positive women and for that of an unborn child (GPP)

- We recommend that potential pharmacokinetic interactions between antiretrovirals, hormonal contraceptive agents and hormone replacement therapy are checked prior to administration (with tools such as: http://www.hiv-druginteractions.org) (GPP)

8.7.3.2 Rationale

Efficacy

There are few data to guide prescribing of initial ART specifically for women, as no RCT in patients starting ART has been powered to detect sex differences in efficacy. From the limited data available, virological outcomes within clinical trial settings generally appear to be no different between men and women.

A meta-analysis of FDA registrational RCTs analysed data from 22,411 HIV positive patients participating in 43 trials for 16 ARVs. Overall 20% of study participants were women. No significant differences in treatment response at week 48 were reported between men and women. Rates of ART discontinuation for virological failure were higher in men (8.15%) than in women (4.25%) [5].

A RCT comparing ATV/r and LPV/r in ART naïve patients of whom 31% were women, a subanalysis showed comparable virological efficacy at week 96 between the two treatment arms in women [6] although virological response rates were lower in women when compared to men.

In a study comparing ATV/r and EFV in 1857 ART naïve patients of whom 17% were women, female sex was associated with increased virological failure on ATV/r compared to EFV [7]. No difference was seen with EFV between men and women.

The efficacy and tolerability of RAL were shown not to be different between men and women at 48 weeks in one study of a diverse cohort of both treatment naïve and experienced patients [8]. RPV in ART naïve men and women showed no difference in rates of virological suppression at 48
and 96 weeks between men and women, but the number of women included was low and the study was not designed to investigate sex differences [9,10].

Cohort studies in the UK have reported similar virological outcomes during the first year of treatment in heterosexual men and women [11]. An Italian cohort study reported no significant effect of gender on clinical progression or the risk of developing a clinical event [12]. Data from Spain in which both naive and ARV experienced women patients showed similar virological responses to men [13].

HIV positive women starting ART should use ARVs from the list of preferred and alternative drugs outlined in Section 5.1 (What to start: summary recommendations). Factors including potential for side effects, drug interactions, patient preference, co-morbidities and dosing convenience need to be taken into consideration when selecting ART regimens in individual women.

**Toxicity, discontinuation and adherence**

Adverse events and treatment discontinuations within ART clinical trials and cohort studies published between 2002 and 2007 have been systematically reviewed. The overall event rate is often the same but the adverse event profile may be different. Women were reported to be more likely than men to experience ART related lipodystrophy, rash, and nausea and also to discontinue therapy [4].

Data from the USA have shown that women are more likely than men to discontinue ART for poor adherence, dermatologic symptoms, neurological reasons, constitutional symptoms and concurrent medical conditions [14]. UK cohort data found 88.6% of men compared to 80.7% of women spent 100% of the first year after starting HAART actually on therapy [11].

Comparison of ATV/r with LPV/r found poorer virological outcomes in treatment naive women compared to men. Gender differences in efficacy were due to higher discontinuation rates in women than men in both treatment arms [6]. Central nervous system side effects of varying severity can occur with EFV, particularly at the initiation of therapy. This may be partly explained by the greater EFV exposure associated with a CYP2B6 variant, more commonly found in Africans and African Americans [15]. In the UK population this is of particular relevance to women a majority of whom are of African ethnicity. NVP associated rash occurs more frequently in women than men [16]. Hepatotoxicity associated with NVP is more common in women with a CD4 count above 250 cells/µL, restricting women’s use of the drug [17].

A systematic review of studies on gender and ART adherence published between 2000 and 2011 in the resource rich world concluded that overall reported adherence is lower in women than men [18]. However of over 1000 studies initially identified for review only 44 had adequate data on gender to allow any comparisons to be made. The authors identified the particular factors for lower adherence in women were depression, lack of supportive interpersonal relationships, young age, drug and alcohol use, black ethnicity ART of six or more pills per day, higher numbers of children, self perception of abdominal fat gain, sleep disturbances and increased levels of distress.
Fetal safety

Concerns about potential fetal toxicity of ARVs have influenced prescribing practice in HIV positive women. Of note, other than ZDV in the third trimester, no ARV drug has a licence for use in pregnancy.

Pregnancy in women living with HIV who are already on effective therapy is increasing; 70% of HIV positive pregnant women in the UK in 2010 were diagnosed prior to the current pregnancy, of whom 60% were already on ART at conception [19]. Where newer drugs are available, women are conceiving on these agents, with ZDV now rarely used as first line therapy for adults. European cohort data comparing pregnancies that were managed with ZDV-containing regimens versus those without ZDV found no difference in risk of detectable viral load at delivery, vertical transmission, or congenital abnormality when comparing ZDV-sparing with ZDV-containing ART [20].

The most robust data on teratogenicity and first trimester antiretroviral therapy exposure are from the Antiretroviral Pregnancy Registry (APR) [21]. This international prospective reporting system records rates of congenital birth defects in babies born to women with exposure to antiretroviral therapy at any stage of pregnancy. 200 or more reports need to be received for a particular compound before data are reported for that compound by the APR. There are now over 200 prospective reports in the APR of first trimester exposure for ABC, ATV, EFV, FTC, 3TC, LPV, NVP, ritonavir, TDF and ZDV. No signal of increased risk of congenital abnormality has been demonstrated, and a greater than 2 fold higher rate than in the general population has been excluded. There are so far fewer than 200 prospective reports for DRV, RAL and RPV within the APR and hence no reports on these agents are yet available.

Despite previous concerns over the safety of EFV based on preclinical animal studies and retrospective case reports in human subjects, the current data do not provide evidence of excess teratogenicity above the expected baseline for infants exposed to EFV in the first trimester. Sufficient numbers of first trimester exposures of EFV have been monitored to detect at least a two-fold increase in risk of overall birth defects within the APR and no such increases have been detected to date [21].

Data from Cote d’Ivoire found no significant increased risk of unfavourable pregnancy outcome in women with first trimester exposure to EFV compared with NVP [22] A systematic review and meta-analysis of observational cohorts carried out in 2010 [23] and further updated in 2011 [24] reported birth outcomes among women exposed to EFV during the first trimester. No increased risk of overall birth defects amongst the babies of women exposed to EFV during first trimester compared with exposure to other antiretroviral drugs was found. The prevalence of overall birth defects with first trimester EFV exposure was similar to the ranges reported in the general population.

A review of live births to women with HIV in a large unselected UK population between 1990 and 2007 found no increased risk of abnormalities in infants exposed to EFV in the first trimester, providing further reassurance that ART in utero does not pose a major risk of fetal anomaly [25]. Mathematical modelling using North American cohort data has demonstrated a theoretical loss of life expectancy in women who delay EFV at initiation of ARV [26].
Based on current evidence, EFV can be initiated in women of child bearing potential, can be continued in women who conceive on the drug and commenced in pregnancy but the data should be discussed in detail with the individual woman when deciding on her preferred treatment regimen. Given that no antiretroviral drug is licensed for use in pregnancy apart from ZDV in the third trimester, a discussion regarding the potential unknown long and short term effects on an unborn child should be had with any woman of childbearing potential who commences any antiretroviral drug regimen. Further details can be found in the BHIVA pregnancy guidelines [1].

**Hormone interactions**

Significant pharmacokinetic and pharmacodynamic interactions have been reported between antiretroviral drugs and hormonal agents. Inducers of hepatic enzymes by ARVs may result in increased breakdown of ethinyl oestradiol and progestogens that can compromise contraceptive and HRT efficacy. Additional contraceptive measures or different antiretroviral regimens may be required in these circumstances. Potential drug-drug interactions should be checked using various resources including specialist HIV pharmacists, web based tools such as the University of Liverpool website on HIV drug interactions and medical information departments in pharmaceutical companies. There is no significant interaction between ETV and the combined OCP, and no interaction is anticipated with RAL. Hormonal contraceptive agents which have been shown not to have a significant interaction or where there is no anticipated interaction include depot medroxyprogesterone acetate, and the levonorgestrol IUS (Mirena coil).

8.7.4 HIV positive women experiencing virological failure

There is very little evidence to guide prescribing ART in HIV positive women experiencing virological failure on ART, with most studies recruiting approximately 10% of women. One study investigating DRV/r in ART experienced patients recruited a large proportion of women and was powered to show a difference in virological efficacy between men and women; this and showed a higher discontinuation rates were among women than men, with nausea being cited as a particular problem but overall there was no difference in virological efficacy [27]. A further study has reported similar efficacy and tolerability of Raltegravir in ART experienced HIV positive women [8].

In HIV positive women experiencing virological failure on ART the same principals of management and recommendations apply as per HIV positive men experiencing virological failure (see Section 7: Management of virological failure)

List of appendices

The Appendices can be found in separate files

Appendix 1: Summary modified GRADE system

Appendix 2: Literature search

A2.2: Questions and PICO criteria

A2.2: Search protocols

Appendix 3: GRADE tables

3.1 Choice of NRTI backbone

3.2 Choice of third agent

3.3 PI monotherapy
